A third PLS method is named \(n\)-PLS, so-called because it is applicable to second-order and higher data.\(^{69,70}\) In the case of three-way data, it is termed tri-PLS. PLS actually consists of two steps. In the first, the data array is decomposed, and in the second, a relationship between the independent (\(\mathbf{R}\)) and dependent (\(\mathbf{y}\)) variables is established. While the array decomposition is trilinear, the part of \(\mathbf{R}\) relevant for describing \(\mathbf{y}\) does not have to be of rank one. This enables calibration in the presence of matrix and other nonlinear effects. The tri-PLS algorithm is based on a decomposition of the data block such that the successively computed score factors have the property of maximum paired covariance with the unexplained part of the dependent variable; this constraint is not met in a trilinear sense with the other Unfold-PLS techniques. In this case, it is assumed that the dependent variables are in the form of a vector, \(\mathbf{s}\), rather than a block of data. This tri-PLS model boils down to the problem of finding the weight vectors \(\mathbf{w}_1\) and \(\mathbf{w}_2\) that satisfy Equation (59):

$$\max_{\mathbf{w}_1, \mathbf{w}_2} \text{cov}(\mathbf{x}, \mathbf{s}) \min \sum_{i=1}^{I} \sum_{j=1}^{J} \sum_{k=1}^{K} (r_{ijk} - x_i w_{1,j} w_{2,k})^2$$ \hspace{1cm} (59)

where \(\mathbf{x}, \mathbf{w}_1\) and \(\mathbf{w}_2\) correspond to the factors for each mode in the decomposition. The least-squares solution to the tri-PLS model is given by Equation (60):

$$\max_{\mathbf{w}_1, \mathbf{w}_2} (\mathbf{w}_1)^T \mathbf{Z} \mathbf{w}_2$$ \hspace{1cm} (60)
where $Z$ is a $J \times K$ matrix formed by $R$ and $s$. The $w_1$ and $w_2$ vectors can be found by performing an SVD on $Z$, and then the scores matrix, $X$, can also be determined. The regression coefficients are calculated according to Equation (61):

$$b = (X^T X)^{-1} X^T S$$  \hspace{1cm} (61)

This method can be extended to higher order arrays with an additional weight vector introduced for each extra way.

The applicability of Unfold-PLS and $n$-PLS can be seen in an example that determines the ash content of sugar.\(^{(69)}\) In the analysis, the fluorescence of 67 samples of sugar was measured at four excitation and 63 emission wavelengths – this produced the $R$ block of data. The $y$ block contained data regarding the ash content of each sample, as determined by a standard European Union method (no. 1265/09). The $R$ and $y$ blocks were divided into a calibration and test set, and mean centering was carried out. The unfolded $R$ block and the $y$ block are shown in Figure 10(a) and (b).

During the analysis, both Unfold-PLS and $n$-PLS used two components to describe the variations in $y$, and the predictions of ash in the test sets were practically identical for both methods (see Table 9) This is due to the fact that the number of samples was large compared with the number of components. However, the difference between the methods is seen in the weight vectors, which show that the solution is much more stabilized in the case of $n$-PLS. (see Figures 11 and 12a and b). The Unfold-PLS weight vectors, especially that of the second component, have incorporated a lot of noise, unlike the tri-PLS vectors, which had fewer parameters to calculate.

### 4 CALIBRATION TRANSFER/STANDARDIZATION

Standardization and calibration transfer are important topics that must often be addressed in order to obtain accurate calibration results.

Many of the multivariate calibration methods that have been discussed have strict requirements when it comes to the characteristics of the data employed and, in particular, these methods perform better when the signal from all analytes in different samples remain constant. Often, however, this is not the case. Consider, for example, an analyte that has been analyzed by LC/MS. If that analyte is analyzed again at a later time, its profile in the new

data will not be identical with that in the earlier sample. Its retention time on the chromatographic axis may have changed, its peak shape may have changed or there may be a combination of both. In order for the second-order calibration to be effective, the differences between the analyte signals in the samples must first be minimized.

The first solution to this problem was proposed by Wang and Kowalski, and was named “second-order standardization”. This method standardizes two-dimensional responses measured on multiple instruments, or on a single instrument under different operational conditions. This technique does not, however, address the case where analyte response is constantly changing from sample to sample.

Second-order standardization is related to a method that exists for first-order (two-way) data, namely piecewise direct standardization (PDS). PDS relates responses of samples measured on different instruments through the use of a banded diagonal matrix, $F$ (Equation 62):

$$\mathbf{R}_1 = \mathbf{R}_2 F$$  \hspace{1cm} (62)

where $\mathbf{R}_1$ and $\mathbf{R}_2$ are a small transfer set of samples measured on instruments 1 and 2 ($\mathbf{R}$ refers to a truncated data set). This method assumes that the response at each channel is related to the response in a small window surrounding that channel on the second instrument. However, in second-order data, an analyte response may vary in both orders from instrument 1 to instrument 2, requiring a second banded matrix to account for changes in the second order. The placement of the banded matrices is (Equation 63):

$$\mathbf{R}_{1,\alpha} = \mathbf{A}\mathbf{R}_{2,\alpha}\mathbf{B}$$  \hspace{1cm} (63)

where $\mathbf{R}_{1,\alpha}$ is the response from sample $\alpha$ on instrument 1 and $\mathbf{R}_{2,\alpha}$ is the response on instrument 2. $\mathbf{A}$ and $\mathbf{B}$ are banded left and right transformation matrices that correct for differences between the responses: these are estimated from a set of simultaneous nonlinear equations via the Gauss–Newton method. It must be noted that the left and right transformation matrices may not be found separately, as their solutions depend upon one another.

Following the estimation of A and B, they may then be used to transfer other samples that have also been run on the second instrument, so that it appears as if they have been run on the first, as (Equation 64):

\[ R_{1,\beta} = AR_{2,\beta}B \] (64)

where \( R_{1,\beta} \) and \( R_{2,\beta} \) are the responses of sample \( \beta \) run on the first and second instruments respectively.

In this way, samples run on instrument 2 can be calibrated using samples run on instrument 1, allowing a laboratory to calibrate their samples using a calibration set from a second laboratory, for example. However, one sample must be run on both instruments, and this transfer sample must have information in all channels, or the transfer will not be optimal. This is because the banded transformation matrices must contain information at all channels that are in new samples to be transferred. An additive correction matrix may be required in addition to Equations (62–64) to correct for additive differences between \( R_1 \) and \( R_2 \). However, a method to find the additive matrix does not currently exist in the literature.

This technique has been tested on LC/UV data, and variation from the ultraviolet (UV) data was found to be reduced from 0.2 AU before the transfer to 0.03 AU after the standardization.

A second standardization method that has been reported for second-order data is “second-order chromatographic standardization”(13). This technique, introduced by Prazen et al., is specifically directed toward data in which one of the orders is a chromatographic separation, while the other order is not chromatographic, e.g. GC/MS. The method corrects for retention shifts between a standard sample and a calibration sample, which allows calibration then to be performed.

In the first step of this method, the pseudo-rank of the sample matrix is estimated, and the two data sets are then augmented. SVD is carried out on the augmented matrix. The remaining eigenvalues beyond the pseudo-rank of the sample are used to calculate the percentage residual variance (\( %RV \)). The retention time of the samples is shifted and the process is repeated until the point is identified where the residual variance is at a minimum. The residual variance calculation is (Equation 65):

\[ %RV = 100 \frac{\sum_{j=n+1}^{c} \lambda_j^0}{\sum_{j=1}^{c} \lambda_j} \frac{c \times r}{(c - n)(r - n)} \] (65)

where \( n \) is the number of chemical components, \( \lambda \) is an eigenvalue and \( c \) and \( r \) are the dimensions of the augmented matrix.

In order to use this standardization method effectively, the pseudo-rank of the sample matrix must be determined, which is not always a straightforward matter. In addition, the test sample must contain the same analytes as the standard sample, which reduces the generality of the procedure. However, the correct use of this technique allows calibration to be carried out with greater accuracy, as was demonstrated on LC/DAD data: methyl vinyl ketone–dinitrophenylhydrazine (MVK–DNPH) in a mixture of five DNPH derivatives was measured, along with two calibration standards, each of which contained only the MVK–DNPH analyte at different concentrations. When GRAM was carried out on the mixture with each of the standards, quantitation was inaccurate (see Table 10). Upon calculation of the \( %RV \) at different time shifts, it was found that one of the analyses required a shift of 0.2 s in the retention time, while the other required a 0.3 s shift, as can be seen in Figure 13.

After the correction, GRAM was performed once again, and the new concentration estimates were drastically improved, as is evident in Table 10. This shows the importance of data quality for accurate GRAM quantitation and the value of standardization in this type of case.

5 STANDARD ADDITION

Standard addition is a method that is commonly employed in zero- and first-order analyses to reduce the effects of
matrix effects on calibration. In order for this method to be effective for zero-order data, there are two assumptions that must be fulfilled. First, the instrument response must vary linearly with analyte concentration. Second, for an analyte response of zero, the instrument response must be zero. The extension to first-order data, generalized standard addition, involves sequential spiking of the sample with the analyte plus each interferent that is affecting the analyte signal. In other words, each source of instrumental signal must be modeled and calibrated. When the data are from an instrument that produces second-order data, however, second-order methods can be used that eliminate this constraint. While the second-order advantage allows calibration in the presence of unmodeled interferents, this is only true when the data are completely bilinear. When there are interferents present in the sample that change the way in which the instrument responds to the analyte, then the data are no longer bilinear. For example, the analyte signal may change in scale or shape depending on the other components that are present in the sample, making traditional calibration unreliable. (Traditional in this sense refers to the second-order calibration methods that rely on the trilinear model.)

A SOSAM that mathematically separates the instrument response of the analyte from the instrument response of any interfering species was proposed by Booksh et al. in order to solve this problem. While trilinear data follow the trilinear model (see Equation 7) which depends on the number of chemical species in the sample \( N \), “fragmented” data follow the model (Equation 66):

\[
R_{ijk} = \sum_{m=1}^{M} X_{im} Y_{jm} Z_{km} + E_{ijk}
\]

where \( M \) is the total number of detectable species formed by the \( N \) chemical components in the sample. This model is applicable in cases where two or more components in a sample mixture combine to form an additional component that can be detected. Matrix effects, on the other hand, occur when two or more sample components interact such that the profiles of the analyte depend on the concentration of the interferent in the sample. Both scenarios result in the data requiring standard addition for reliable calibration.

There are three steps to the SOSAM. The data block, \( \mathbf{R} \), must first be decomposed. This can be achieved using any of the second-order methods already mentioned, such as DTD or PARAFAC. Following this step, the \( N \) columns in the sample space of \( \mathbf{R} \) (i.e. \( \mathbf{Z} \)) must be regressed against the standard additions to obtain \( N \) concentration estimates. For zero-order standard addition, a least-squares model is used (Equation 67):

\[
r_k = \delta_k m + b
\]

where \( r_k \) is the instrument response for the \( k \)th sample, \( \delta_k \) is the change in analyte concentration from the first to the \( k \)th sample (from the standard additions) and \( m \) and \( b \) are the slope and intercept of the regression line, respectively. Using this model, the estimated analyte concentration in the original (first) sample is given by Equation (68):

\[
\hat{c} = \frac{b}{m}
\]

For the extension to second-order data, \( \mathbf{Z} \) is the equivalent of \( r_k \) in Equation (65), because whether the data are bilinear or fragmented, there will be one column of \( \mathbf{Z} \) that...
is linearly related to the analyte of interest. Equation (69) shows how the slope and intercept may be calculated in the second-order case, so that Equation (68) may then be used to calculate the analyte concentration:

\[ \hat{z}_n = \delta m + b \]  

(69)

Following the regression, a decision may have to be made as to which concentration estimate is correct. This will be the case when the data are fragmented, as there will be a number of concentration estimates, each of which will relate to a different factor. For example, there will be unique factors for both the interferent and analyte, but there may also be factors that relate to the interactions between them, in addition to factors that describe nonlinearities. The analyte concentration estimate may be determined as the smallest estimate that does not change when additional standard additions are included in R.

When applied to bilinear data, this algorithm is robust to shifting errors, and the bias in concentration estimates is low. Calibration in the case of fragmented data results in a low bias when the data are nondegenerate. When the algorithm is applied to degenerate data, however, the effect of random errors is increased. This may occur, for example, when two components have a common profile in one of the orders and therefore cannot be resolved.

This technique has been applied to a data set that resulted from the collection of UV diode-array spectra over a 30 min time period, over the course of a Fujiwara reaction. Trichloroethylene (TCE) in the presence of chloroform (CHCl₃) was quantified, and six standard additions of TCE were made. It had previously been discovered that TLD fails to predict the concentration of TCE in the presence of large quantities of CHCl₃, owing to an interaction between the two reagents. In that case, the prediction error was found to be 29.5%. However, the data were determined to be fragmented and degenerate, therefore the model in Equation (64) applies. The prediction error was 10.8% when all six standard additions were included in the calculation, which is an improvement over the TLD error of 29.5%. Furthermore, when only the four most linear standard additions were used in the analysis, the error decreased to 2.6%, while TLD produced an error of 30.0% for the same standards.

6 FIGURES OF MERIT

Figures of merit provide a means of determining how well analytical determinations, including calibrations, perform. These performance characteristics include sensitivity, selectivity and S/N, in addition to net analyte signal. For good calibration, a high sensitivity and selectivity are desirable, as is a high S/N. A high sensitivity indicates that the analyte response changes significantly with concentration, which is important since small concentration changes may then be detected. Selectivity, on the other hand, is a measure of how well the method can distinguish the analyte in question from other analytes. This characteristic is related to the net analyte signal, which calculates the proportion of the signal unique to the analyte. A high net analyte signal translates into a high selectivity. Taken together, these characteristics can be used as criteria to decide whether or not a given instrument is suitable for attacking a particular analytical problem, or they can be used to determine the optimal set of analytical conditions for the problem.

The figures of merit mentioned above are well defined for zero-order data: the net analyte signal can be obtained simply by performing a background subtraction, while the sensitivity is determined from the slope of the calibration curve. Work by Lorber allowed them to be calculated for first-order data, and there has also been research in the area of second-order figures of merit. The derivation of the second-order figures of merit is much more complicated than the zero- and first-order versions, owing to the added complexity of the data. To date, there have been derivations only for bilinear data matrices.

Most figures of merit are related to the net analyte response, Rₖ, which for the kth analyte in a second-order data matrix, R, can be defined as (Equation 70):

\[ R^*_k = P_{k,x}R_{k,y} \]  

(70)

where (Equations 71a and 71b):

\[ P_{k,x} = I - X_{-x}X^*_{-x} \]  

(71a)

\[ P_{k,y} = I - Y_{-y}Y^*_{-y} \]  

(71b)

While the net analyte response is a matrix that contains the profile of that part of the analyte signal that is orthogonal to every other component in the matrix, the net analyte signal, rₖ, is a scalar that is derived from the net analyte response (Equation 72):

\[ r^*_k = \text{vec} R^*_k \]  

(72)

where \( \| \| \) refers to the Euclidean norm, and the vec operator corresponds to “vectorizing” the matrix. Selectivity, lₖ, and sensitivity, sₖ, are both found using the net analyte signal as (Equations 73 and 74):

\[ l_k = \frac{r^*_k}{\| \text{vec} R^*_k \|} \]  

(73)

\[ s_k = \frac{r^*_k}{c_k} \]  

(74)
A selectivity of zero implies that an analyte signal cannot be distinguished from other analytes— in other words, the net analyte signal is completely overlapped by other analyte signals. A selectivity of 1, on the other hand, means that the net analyte signal is not at all overlapped by other analyte signals.

These equations can be extended to \(n\)th-order data by using the \(\text{vec}\) operator to string out the data. Carrying this out on second-order data (e.g. Equation 2) produces Equation (75):

\[
\text{vec} R = \sum y_k \otimes x_k
\]  

(75)

where \(\otimes\) is the \(N\)-fold Kronecker product.\(^{(14)}\) Similarly, the \(\text{vec}\) operator can be applied to three-way arrays such that (Equation 76):

\[
\text{vec} R = \sum_{k=1}^{K} \sum_{n=1}^{N} a_{k,n}
\]  

(76)

where \(A_{n} (n = 1, \ldots, N)\) is a factor matrix of \(R\) instead of \(X\) and \(Y\). The net analyte response may then be denoted by Equation (77):

\[
\text{vec} R_{k} = \left( \bigotimes_{n=1}^{N} P_{k,n} \right) \text{vec} R = P_{k} \text{vec} R
\]  

(77)

As is the case with the second-order data, all of the figures of merit may be calculated from the net analyte response.

The second-order selectivity is one of the most important figures of merit for calibration, as a low value means that quantitation will be very difficult in the presence of interfering species. Selectivities of analytes in LC/DAD spectrochromatograms have been calculated, and serve to demonstrate typical values based on overlapped chromatograms and spectra in a data matrix. The analytes are toluene, naphthalene and \(m\)-xylene, all of which are spectrally similar, and biphenyl, which is spectrally dissimilar. The pure spectra and chromatograms are shown in Figure 14(a) and (b).

Upon calculation with Equation (73) for each analyte, the values in Table 11 were obtained. The first-order selectivities for the spectra of these analytes are shown in Table 12 for comparison.

The second-order selectivities can be explained based on the signals in the two orders (chromatographic and spectroscopic). For example, the largest value is for the comparison of naphthalene and biphenyl. When the first-order selectivity for this combination is examined, it can be seen that it is high, meaning that these analytes are the most dissimilar spectrally; moreover, the chromatographic profiles show that they are also the most dissimilar in that axis, resulting in the high second-order selectivity. On the other hand, \(m\)-xylene and biphenyl have the lowest selectivity, implying that
the signals from these analytes are more similar than any of the others. While their spectral similarity is not the highest (as seen by the relatively low first-order selectivity), their chromatographic profiles are very much overlapped, and this is what leads to their low second-order selectivity.

7 FUTURE WORK

While there have been tremendous advances in the area of second-order calibration, much work remains. Some of that work will pertain to improving the robustness and speed of the algorithms, while another part of the work should focus on increasing the awareness of the analytical community as to the value of such tools. Generally, while two-dimensional instruments are commonly used in today’s laboratories, analysts often reduce the huge amount of data produced to one-dimension, and consequently they also reduce the quantity of information present. For example, when LC/MS is used, a two-dimensional data array is produced, but these data are often only viewed as a total ion chromatogram plot, thereby losing the mass spectral information. Often, the analysts are not aware of the existence of second-order methods. However, when this is not the case, the techniques are still not used owing to the perceived difficulties in their application. The great difficulty, therefore, is with the transfer of technology from the research arena to industry. Once this occurs, the use of second-order tools, including calibration, will become common place.

REFERENCES

Signal processing refers to a variety of operations that can be carried out on a continuous (analog) or discrete (digital) sequence of measurements in order to enhance the quality of information it is intended to convey. In the analog domain, electronic signal processing can encompass such operations as amplification, filtering, integration, differentiation, modulation/demodulation, peak detection, and analog-to-digital (A/D) conversion. Digital signal processing can include a variety of filtering methods (e.g. polynomial least-squares smoothing, differentiation, median smoothing, matched filtering, boxcar averaging, interpolation, decimation, and Kalman filtering) and domain transformations (e.g. Fourier transform (FT), Hadamard transform (HT), and wavelet transform (WT)). Generally the objective is to separate the useful part of the signal from the part that contains no useful information (the noise) using either explicit or implicit models that distinguish these two components. Signal processing at various stages has become an integral part of most modern analytical measurement systems and plays a critical role in ensuring the quality of those measurements.

1 INTRODUCTION

The reliability of analytical results is vitally dependent on the quality of the measurements leading to their determination. Signal processing refers to a variety of operations that can be carried out on a continuous or discrete sequence of measurements in order to enhance the quality of information they are intended to convey. The term ‘signal’ is ordinarily applied to a sequence of measurements that are related by some ordinal variable, such as time or wavelength, and usually obtained via electrical transduction. Operations can be carried out on a continuous electrical signal (analog signal processing) or on discretely sampled numerical values (digital signal processing). Generally, the objective is to separate the desired part of the signal (the pure signal, which is correlated to some physical or chemical property of interest) from the unwanted part of the signal, or noise. Often, the term ‘signal processing’ implies that operations are carried out in real time, or as the data are acquired, but this is not a requirement. The distinction between signal processing and other forms of data analysis is often open to interpretation, but usually signal processing emphasizes alternative representations of the sequence of measurements as opposed to the direct extraction of secondary information such as analyte concentrations or chemical structures.

The goal of this article is to provide an overview of signal processing methods used in analytical chemistry with an emphasis on their capabilities, weaknesses, and practical implementation. Although both analog and digital signal processing are discussed, a much greater emphasis is placed on the latter because of its greater relevance to the practicing analytical chemist. Owing to the scope of the subject area, some topics will no doubt be neglected or underemphasized, but an attempt has been made to balance coverage with the importance to the field.
2 OVERVIEW

2.1 History

Historically, signal processing in analytical chemistry can be regarded as originating with the first quantitative analytical measurements, such as the end-point of a titration, the potential of an electrochemical cell, or the absorbance of a solution at a single wavelength. Such scalar quantities are now sometimes referred to as zero-order measurements, with reference to the fact that a scalar is a zero-order tensor. Rudimentary signal processing consisted of averaging replicate measurements or damping the response of electrical signals, but these were rather simplistic approaches when compared to today’s more sophisticated methods.

The evolution of modern signal processing in analytical chemistry can be traced to three parallel developments. The first was the emergence of analytical instruments capable of producing first-order data, or a vector (first-order tensor) of measurements. The development of instruments such as chromatographs and scanning spectrometers meant that the signal from an instrument could no longer be considered static, but rather changed in a regular fashion with some variable such as time or wavelength, thereby requiring more flexible signal processing methods that could remove the noise without distorting the pure signal. A second important influence was the appearance of the analog-to-digital converter (ADC) and the computers that drove them. This opened the door to more versatile digital signal processing methods. Finally, there was the parallel development of efficient digital signal processing algorithms, such as the Savitzky–Golay (SG) implementation of polynomial least-squares filters and the Cooley–Tukey algorithm for the fast Fourier transform (FFT), which are still among the most highly cited papers in the literature. Such algorithms made the practical implementation of signal processing methods a reality.

Although first-order instruments are still the mainstay of analytical chemistry, second-order instruments which provide a matrix of data, such as chromatographs with multichannel detection and tandem mass spectrometers, are now routinely employed, and higher-order instruments are commonplace. These, combined with ever more powerful computational platforms, have advanced modern signal processing to yet another level.

2.2 Definitions and Notation

Throughout this article, the term ‘signal’ will be used to refer to either a continuous or discrete measurement sequence which consists of a pure or undistorted signal corrupted by noise. The signal is implicitly measured as a function of some other variable which will be referred to as the ordinal variable because it correlates directly with the sequence order. Traditionally, this variable is time, but other variables such as wavelength or applied voltage (which may or may not be correlated with time), can be employed without loss of generality. References to representation of the signal in the ‘time domain’ will therefore refer to the original measurement sequence even if the ordinal variable is not time. Likewise, references to ‘frequency domain’ representations (section 3) will refer to a FT (section 6) into the inverse domain of the ordinal variable.

The term ‘noise’ is used to refer to unwanted fluctuations from the pure signal that obscure its measurement. This definition is quite general and means that what is considered noise can vary with the situation. If a signal consists of contributions from two sources, A and B, then B is considered noise if one is looking for A, and vice versa. Noise, especially random noise, is often characterized by its root-mean-square (rms) amplitude (continuous signals) or by its standard deviation (discrete signals).

Most of this article concerns digital signal processing methods where the signal is a vector of discrete measurements, usually made on equal intervals of the ordinal variable referred to as the sampling interval, \( t_s \). The reciprocal of this interval will be referred to as the sampling frequency, \( f_s \). (Again, analogous definitions hold when the ordinal variable is not time.) In vector notation, the signal \( \mathbf{x} \) is the result of combining the pure signal vector \( \mathbf{x}^0 \) with the noise vector \( \mathbf{e} \) (Equation 1):

\[
\mathbf{x} = \mathbf{x}^0 + \mathbf{e}
\]  

(1)

Throughout this article, boldface lower case letters are used to represent vectors (assumed to be column vectors unless otherwise indicated). Scalar quantities will be represented by lower case italic letters and matrices by boldface upper case letters. Transposes of vectors or matrices will be indicated with a superscript ‘\( \top \)’ and inverses of matrices with a superscript ‘\( -1 \)’. The identity matrix will be designated ‘\( \mathbf{I} \).

3 SIGNALS AND NOISE

3.1 Signals and Signal Domains

The features that distinguish a signal from a random series of measurements are: the measurements have a definite order, and the measurements are generally correlated in the time domain. For a discrete signal undistorted by noise, \( \mathbf{x}^0 = [x_1^0, x_2^0, x_3^0, \ldots] \), the correlation of two measurements is described by their covariance (Equation 2),

\[
\text{cov}(x_1^0, x_2^0) = \mathbb{E}(x_1^0x_2^0)
\]  

(2)
where ‘E’ denotes the expectation value. To say that two measurements are correlated means that knowing one allows us to say something about the other. Although the covariance among measurements in a sequence is not generally known, some knowledge of its characteristics may be known, and it is these characteristics that are often used to distinguish the pure signal from the noise. For example, if the pure signal changes relatively slowly, it exhibits long-range correlations which may not be present in the noise.

Although signals are usually presented in the time domain, the same information can be conveyed by transforming them in alternate domains. The most useful of these is the frequency domain. For a continuous signal, this transformation can be accomplished by using a spectrum analyzer, a device that consists of a continuous series of electronic bandpass filters. The signal, which must be repetitively applied to the input of the device, is filtered by the spectrum analyzer and the rms signal at each frequency is determined. In essence, the power of the signal is plotted as a function of frequency to give a power spectrum. In the age of discrete signals, this approach is rarely used anymore, instead being replaced by the discrete FT, which is the digital counterpart of the analog spectrum analyzer. FTs are discussed in more detail in section 6 but, because of their importance to signal processing, they are introduced here. All of the information conveyed in the original signal is carried in the FT, but it is represented in the frequency domain rather than the time domain. This allows the composition of the signal in terms of sinusoidal frequencies to be analyzed, providing more direct information about the correlations in the time domain. Slowly varying signals in the time domain will have significant low-frequency components, and the shape of the power spectrum conveys important information about optimal signal processing methods. Figure 1 shows some simple signals and their FTs. The first example shows that a pure sinusoid gives rise to a single peak in the frequency domain. In contrast, the sharp edges of the square wave in the second example lead to high-frequency components in the FT. The last two examples demonstrate that more slowly varying signals have fewer high frequency components.

3.2 Noise

The noise in an analytical signal can be classified in a number of ways, including (a) its distribution, (b) its source, (c) its characteristics in the time domain, and (d) its characteristics in the frequency domain. Because different classifications are used in different situations and they are not all mutually exclusive, it is necessary to understand the different cases and how they relate to signal processing. In doing so, it is helpful to imagine a signal from which we could subtract the pure signal component leaving only the noise or, alternatively, a situation in which the pure signal is zero so that we are measuring only noise, as shown in Figure 2(a).

If we were to plot a histogram of the magnitude of the noise for a large number of measurements, we might obtain a distribution such as that shown in Figure 2(b). By far the most common noise distribution (assumed or measured) for analytical measurements is the normal, or Gaussian, distribution, shown by the solid line in the figure. The reason for this is the central limit theorem which, simply put, states that if a measurement is the sum of a series of values drawn from arbitrary distributions, the distribution of the measurement will approach a normal distribution as the length of the series approaches infinity. As, in an analytical instrument, the observed noise is a consequence of many smaller random events, the central limit theorem can be rationalized to hold. Other noise distributions (e.g. uniform, log-normal) are also observed but are much less common. One other type which is common, however, is the Poisson distribution, which is observed in cases where the signal arises from
Figure 2 Representations of white noise: (a) noise sequence in the time domain, (b) distribution, (c) autocorrelation function, (d) FT.

a collection of discrete events, such as photons striking a photomultiplier tube. However, in reality a histogram constructed from Poisson noise would look essentially the same as the normal distribution in most cases. The distinction is in how the magnitude of the noise (i.e. its standard deviation) changes with signal intensity. The standard deviation of Poisson noise will increase with the square root of the signal intensity. To say that noise has a normal distribution, however, does not imply anything about how its magnitude changes with signal intensity. In this sense, the Poisson distribution can be regarded as a special case of the normal distribution.

In some cases noise is classified according to its dominant source. Such classifications often imply information about the distribution or temporal characteristics of the noise. For example shot noise, also called Schottky noise or quantum noise, arises in detectors based on discrete events, such as photons striking a photomultiplier, and exhibits a Poisson distribution. Shot noise is a type of fundamental noise because it originates from the random statistical nature of the events themselves and not from any deficiencies of the instrument. This type of noise dominates in cases where the number of events is relatively small, such as in fluorescence measurements. Johnson noise is another type of fundamental noise that arises from the random thermal motion of electrons in resistors. Flicker noise is considered to be a type of non-fundamental or excess noise in which the magnitude of the noise is directly proportional to the signal amplitude, hence it is often referred to as proportional or multiplicative noise. Flicker noise is often associated with variations in source intensity in absorption spectroscopy and can have distinctive frequency characteristics (see below). Other types of noise include interference noise (electrical, optical or other interferences that arise at specific frequencies, such as 60 Hz line interference), detector noise (a general term referring to instruments in which the limiting noise, such as shot noise or thermal noise, occurs at the detector), amplifier-readout noise (the noise observed for the readout circuitry when the input signal is zero) and quantization noise (observed when measurement precision is limited by the A/D conversion step).

In the time domain, noise can be classified in two ways: correlated and uncorrelated. Uncorrelated, or independent, noise implies that the noise observed at one point in the series of measurements is not related
in any way to that at other points. If we consider the sequence of noise to be represented by the vector \( e_1, e_2, e_3 \ldots \), then the covariance between the first two noise elements can be represented by Equation (3),

\[
\sigma_{12} = E(e_1 e_2)
\]

and will be zero for uncorrelated noise. In many applications, independent and identically distributed noise with a normal distribution, or \textit{iid normal} noise, is assumed, implying uncorrelated noise with a Gaussian distribution and equal variances at all channels. However, in reality correlated noise is commonplace, arising from varied sources such as temporal variations in spectroscopic source intensities, spatial correlations (cross-talk) in array detectors, thermal variations and electronic filtering. Signal processing itself can turn uncorrelated noise into correlated noise, a fact that can be important for subsequent data analysis methods. The correlation of a noise sequence can be examined through its autocorrelation function. This is obtained through an element-by-element multiplication of the noise sequence by a time shifted version of itself and averaging the results of the \( n \) multiplications. This is repeated for each time shift. Uncorrelated noise should give a single spike at zero time delay, with the products averaging to zero everywhere else. This is demonstrated in Figure 2(c).

The complete characterization of the correlation among elements of a noise vector of length \( n \) is given by the error covariance matrix \( \Sigma \) (Equation 4):

\[
\Sigma = \begin{bmatrix}
\sigma_1^2 & \sigma_{12} & \cdots & \sigma_{1n} \\
\sigma_{12} & \sigma_2^2 & \cdots & \sigma_{2n} \\
\vdots & \vdots & \ddots & \vdots \\
\sigma_{1n} & \sigma_{2n} & \cdots & \sigma_n^2
\end{bmatrix}
\]

where the diagonal elements represent the noise variances and the off-diagonal elements (zero for uncorrelated noise) represent the covariance. If a noise sequence is a stationary process, then its statistical properties remain constant throughout the sequence, which means \( \sigma_{12} = \sigma_{23} = \sigma_{34} \) and so on. The terms ‘homoscedastic’ and ‘heteroscedastic’ are also used to indicate whether the variance of the noise remains constant or changes with the position in the series, respectively.

As with the signal, the characteristics of the noise can be examined in the frequency domain by using a spectrum analyzer or the FT. The result is called the noise power spectrum (NPS) and it conveys important information about the time domain correlations of the noise. Uncorrelated noise is referred to as white noise and, analogous to white light, it contains equal contributions at all frequencies. This is the type of noise that is often assumed or hoped for when designing or implementing signal processing methods, but exceptions are very common. The NPS for the white noise in Figure 2(a) is shown in Figure 2(d). Note that because of the stochastic nature of noise, the NPS is not perfectly flat.

Often purely white noise is corrupted by pink noise or 1/f noise. This noise, also known as drift in the time domain and arising from flicker noise, has a NPS which varies as the reciprocal of the intensity. The dominance at low frequencies is indicative of correlated noise in the time domain. The third type of noise readily identified in the NPS is interference noise, which appears as spikes at the corresponding frequencies and often higher harmonics. Figure 3 illustrates a typical correlated noise sequence and its representative autocorrelation function and NPS. Note the slow decay of the autocorrelation function indicating that the noise is not white. Both 1/f noise and interference noise are apparent in the NPS. It should be noted that, in order to obtain a clear representation of the autocorrelation function and the NPS in this case, it was necessary to average results from 20 noise sequences, because a single noise sampling does not usually give a clear indication of its characteristics.

### 3.3 Signal Averaging

One of the most effective ways to separate the pure signal from the noise is through the use of signal averaging. True signal averaging, as opposed to boxcar averaging or smoothing (section 5), requires a repetitive signal sequence. A common example is the fluorescence or phosphorescence decay curve generated by pulsing a laser or flash lamp repetitively. Each experiment (pulse) results in a signal that can be added to the next, and the total sum can be averaged over the number of experiments. Unlike most of the methods described here, which take advantage of signal correlation within a single experiment, signal averaging exploits signal correlation at a given time channel for repeated experiments. For this reason, it is discussed here, separately from the other techniques.

In order for signal averaging to be effective and useful, a number of conditions need to be met. First, the noise should be uncorrelated between corresponding time channels for successive experiments or else it will not be effectively removed. (Note that correlation of noise within an experiment is not important.) A second requirement is that the shape of the signal needs to be truly repetitive in the time domain. Translation of the signal or changes in its profile (other than scaling) due to poor synchronization or changes in the process will lead to an unrepresentative average, although noise should be reduced. Finally, the duration of the experiment needs to be short enough to make signal averaging practical.
When these conditions are met, signal averaging can be particularly advantageous because: (a) the signal-to-noise ratio (SNR) improves by a factor of \( \sqrt{n} \), where \( n \) is the number of repetitions, and (b) there is no distortion in the profile of the signal. In contrast, most of the methods discussed in the sections that follow have the potential to distort the shape of the signal.

4 ANALOG SIGNAL PROCESSING

4.1 Overview

As virtually all instrumental methods involve some form of electrical transduction of a particular phenomenon into a continuous signal, analog signal processing is as universal as it is diverse. Such processing begins the moment the quantity being measured is converted into some electrical property such as current or voltage (assuming that it did not originate in that form) and continues until the final measurements are recorded in digital or analog form. This obviously opens up a tremendous range of topics, the detailed coverage of which is beyond the scope of this article. However, there has been a gradual shift over the years which has placed an increasing emphasis on digital signal processing over analog signal processing. One reason for this is that access to the analog signal in modern instruments has become more restricted and more often the chemist is presented with data that have already been digitized, as evidenced by the demise of the chart recorder from most analytical labs. A second reason is that improvements in the speed and storage capacity of digital components have removed many of the limitations of early devices. Finally, digital processing of results has the advantage that it can be carried out any time after the data are required, whereas this is not true for analog signal processing.

On this basis, it could be argued that a detailed comprehension of analog signal processing is less important now than it once was, although it is still essential to understand the basic capabilities and limitations of this stage of processing, because it will always precede the generation of digital information and can be the ‘weak link in the chain’ if care is not taken. For this reason, a brief coverage of electronic signal processing methods is presented here, with a special emphasis on two aspects which are closely related to digital processing, analog filters and A/D conversion.

The electronic manipulation of signals can be divided into methods which are based on passive or active
Most complex manipulations of electronic signals are based on operational amplifiers, active circuit elements employed for a wide variety of linear and nonlinear operations. A basic operational amplifier, represented symbolically in Figure 4(a), is essentially a high gain (typically $10^5$) differential amplifier. By taking advantage of the high gain in negative feedback, the two inputs (referred to as the inverting (−) and noninverting (+) inputs) and the output can be configured into a wide range of useful circuits using passive components. As an example, the configuration for a simple fixed-gain voltage amplifier (gain $V_{out}/V_{in} = (R_1 + R_2)/R_2$) is shown in Figure 4(b).

The number of electronic operations that can be carried out on electrical signals is too extensive to cover here, but a brief summary of some important operations is given in Table 1. More details on analog signal processing can be found in appropriate references on the subject. Analog filters and A/D conversion are also covered in more detail in sections 4.2 and 4.3.

### 4.2 Analog Filters

One of the simplest operations that can be carried out to improve signal quality is the application of an electronic filter. As the object of signal processing is to distinguish the pure signal from the noise, a means

<table>
<thead>
<tr>
<th>Operation or circuit</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Domain conversion</td>
<td>Conversion of an analog signal between domains, such as current-to-voltage, resistance-to-voltage, time-to-amplitude, A/D.</td>
</tr>
<tr>
<td>Amplification</td>
<td>Multiplication of an analog signal by a constant factor called the gain. Sometimes coupled with domain conversion.</td>
</tr>
<tr>
<td>Inversion</td>
<td>Changes the sign of an analog signal.</td>
</tr>
<tr>
<td>Addition/subtraction</td>
<td>Two or more signals are added/subtracted.</td>
</tr>
<tr>
<td>Multiplication/division</td>
<td>Two signals are multiplied/divided by one another. Often used with modulation (see below).</td>

<tr>
<td>Integration/differentiation</td>
<td>Includes logarithm, antilogarithm, absolute value, reciprocal, etc.</td>
</tr>
<tr>
<td>Modulation</td>
<td>Process by which the property (e.g. amplitude or frequency) of a carrier wave, typically a high frequency sinusoid or square wave, is modified to convey information about an analog signal of interest. Demodulation is used to recover the original analog signal.</td>
</tr>
<tr>
<td>Comparator</td>
<td>Circuit that compares two voltages and produces one of two outputs, depending on which signal is larger.</td>
</tr>
<tr>
<td>Pulse height discriminator</td>
<td>Circuit that detects the presence of pulses with a peak amplitude within a certain threshold region.</td>
</tr>
<tr>
<td>Peak detector</td>
<td>Circuit that follows an analog signal until it reaches a peak value and then holds that value for a certain time period.</td>
</tr>
<tr>
<td>Sample-and-hold amplifier</td>
<td>Circuit that samples an analog voltage at a particular point in time and holds the value until further processing, normally A/D conversion, is completed.</td>
</tr>
<tr>
<td>Boxcar integrator</td>
<td>Circuit used to measure a rapidly changing but repetitive signal by sampling it after a particular delay time and holding the sampled measurement. Often the delay time is scanned to obtain the time profile of the signal.</td>
</tr>
<tr>
<td>Lock-in amplifier</td>
<td>One type of circuit used to demodulate analog signals (see above).</td>
</tr>
</tbody>
</table>
is generally sought to distinguish the two. As noted in section 3, this distinction can often be made in the frequency domain. Typically, white noise has a flat NPS, whereas a slowly varying signal will have most of the information at low frequencies. Therefore, a filter that removes high-frequency components from a noisy signal, called a low-pass filter, will retain most of the information about the pure signal while eliminating much of the noise. However, drift and offset noise (low frequency) may be dominant features in the noise, and a high-pass filter may be more effective, provided there are sufficient high-frequency components in the signal. In another scenario, the signal may be modulated at a particular frequency and it may be necessary to use a band pass filter to isolate the components of interest. Finally, if interference noise, such as 60 Hz noise, is a problem, it may be removed using a notch filter. The ideal transfer functions for each of these types of filter is shown in Figure 5. The transfer function gives the amplification or gain of the filter as a function of the frequency of the input and ideally should be unity within the pass band and zero in the stop band.

As shown in section 5, analog filters bear many similarities to digital filters, but it is important to understand the former for several reasons. First, analog filters evolved before digital filters and there is substantial overlap of terminology. Second, although digital filters are becoming more widely used, analog filters are often a more effective way to eliminate noise near the source and are essential to limit the noise bandwidth in any digital data acquisition system. Finally, although they share similarities in their characteristics, transfer functions for digital and analog filters are significantly different.

Analog filters can be classified as either active or passive. Passive filters use only resistive (i.e. resistors) and reactive (i.e. capacitors and inductors) components, whereas active filters employ operational amplifiers as well. Figure 6 shows examples of simple low-pass and high-pass resistor–capacitor (RC) filters. In principle, filters could also be constructed using resistors and inductors, but inductors tend to be more bulky, expensive and less ideal, so in practice capacitors are more commonly used. The transfer function for a simple low-pass filter is shown in Figure 7(a). The gain is given by the ratio of the capacitive reactance to the total impedance
(Equation 5):

\[
\text{gain} = \frac{V_{\text{out}}}{V_{\text{in}}} = \frac{X_C}{Z} = \frac{1/(2\pi fC)}{\sqrt{R^2 + 1/(2\pi fC)^2}} = \frac{1}{\sqrt{(2\pi fRC)^2 + 1}}
\]

(Equation 5)

Here \( X_C \) is the capacitive reactance, \( Z \) is the total impedance of the circuit, \( f \) is the frequency in hertz, \( R \) is the resistance in ohms, and \( C \) is the capacitance in farads. Note that the voltages referred to in this equation are not instantaneous voltages, but rather peak or rms values for inputs of a fixed frequency, as analog filters usually impose a phase shift on the original signal. More commonly, the frequency response of a filter is shown with a Bode plot, in which logarithmic scales are used on both axes. The voltage gain on the vertical axis is normally expressed in decibels (dB), given by Equation (6):

\[
\text{gain(dB)} = 20\log \left( \frac{V_{\text{out}}}{V_{\text{in}}} \right)
\]

(Equation 6)

A Bode plot for a simple low-pass filter is shown in Figure 7(b). The frequency cut-off is usually taken to be the point at which the capacitive reactance equals the resistance, i.e. \( V_{\text{out}}/V_{\text{in}} = 1/\sqrt{2} \). This corresponds to a gain of \(-3.01 \text{ dB} \), and so the operational cut-off frequency is usually referred to as the ‘3 dB point’. The cut-off frequency depends on the product \( RC \) and, for the simple low pass filter shown in Figure 6, this is given by Equation (7):

\[
f_{\text{cut-off}} = \frac{1}{2\pi RC}
\]

(Equation 7)

After the cut-off frequency, the Bode plot shows a linear region which has a slope of \(-20 \text{ dB per decade} \), more gradual than the ideal case shown in Figure 5. In order to provide a steeper slope, the order of a filter has to be increased. The filter order, also referred to as the number of poles, is the number of reactive components required for each cut-off frequency. Therefore, a first-order low- or high-pass filter such as the ones above requires only one capacitor, whereas a band-pass filter would require two. The higher the order of the filter, the more one can approach the ideal filter with a sharp transition between the pass band and the stop band. Practical limitations related to loading and other factors restrict the number of poles that can be used with passive filters, however, and active filters are normally used when more sophisticated filters are required.

The use of operational amplifiers in active filters allows greater flexibility in filter design. The design of active filters is well beyond the scope of this article, but fortunately, in those cases where a chemist may wish to incorporate an active filter, standard designs have been developed.\(^3\) An active filter is classified not only according to its order, but also according to the way it optimizes a variety of other parameters, such as the steepness of the transition region, the flatness of the pass band, and its phase characteristics. Two of the most common types are the Butterworth, or maximally flat, filter and the Chebyshev, or equal ripple, filter. As shown in Figure 8, the frequency response of the Butterworth filter is very flat in the pass band, but its transition region is not as steep as the Chebyshev filter, which exhibits ripples in the pass band. The design for this active filter is shown in Figure 9. Note that the difference between the two filter types lies simply in the selection of the components and that the ripple can always be decreased at the expense of sharpness. The implementation of these filters is made even simpler through the use of integrated circuits incorporating switched capacitor filters that allow the cut-off frequency to be set simply with a reference clock signal.

From a digital signal acquisition perspective, perhaps the most important kind of filter is the anti-aliasing filter. When a signal is converted from the analog domain into the digital domain, it must be sampled at discrete and normally equally spaced time intervals, \( \Delta t \). The sampling frequency is given by \( f_s = 1/\Delta t \), and restricts the
Figure 10 An illustration of aliasing in which open circles indicate sampled points. Parts (a) and (b) represent signals below the Nyquist frequency which are not aliased. The solid lines in (c) and (d) represent signals above the Nyquist frequency which are aliased to lower frequencies (dashed lines).

upper limit of signal frequencies that can be accurately represented in the transition from A/D information. More specifically, any components of the signal with frequencies above the Nyquist frequency will have their components aliased to lower frequencies. The Nyquist frequency, $f_N$, is given by Equation (8):

$$f_N = \frac{f_s}{2} = \frac{1}{2\Delta t}$$  \hspace{1cm} (8)

The phenomenon of aliasing is shown in Figure 10, where four different sinusoids are sampled at a frequency of 1 Hz (i.e. $f_N = 0.5$ Hz). The first two signals shown are below the Nyquist frequency and the sampling reflects their variations accurately. However, the last two signals are above the Nyquist frequency and aliased back to lower frequencies (Figure 10).

The importance of an anti-aliasing filter, which is simply a low-pass filter with a cut-off near the Nyquist frequency, has to do with the noise bandwidth of the analog signal. If noise components are present above the Nyquist frequency and no filtering is applied, this noise will be aliased back to lower frequencies and appear in the acquired signal. As no information at frequencies higher than the Nyquist frequency can be accurately extracted anyway, it is wise to always use an anti-aliasing filter to reduce noise in a digitally acquired signal. Also note that this noise can only be removed in the analog domain and digital filtering cannot help once the noise is aliased to lower frequencies.

4.3 Analog-to-digital Conversion

A/D conversion refers to the process by which a continuously variable analog signal, usually a voltage, is converted into a discrete numerical value with a fixed precision. In most modern analytical instruments, A/D conversion is a key step in the signal processing sequence. Although this process is generally transparent to the user, an understanding of the principles involved can be useful in practice.

As digital logic circuits are based on binary states, the digital representation of a measurement is made in the binary, or base 2, number system, consisting of a series of binary digits, or bits. Thus the number 27 in base 10 would be represented by the following 8 bits, or byte, in base 2:

$$27_{10} = 0001\ 1011_2$$

Alternatively, binary coded decimal (BCD) can be used in which each series of 4 bits (sometimes called a nibble) represents a decimal digit:

$$27_{10} = 0010\ 0111 \text{ (BCD)}$$

For $n$ bits, a binary representation gives the numbers from 0 to $2^n - 1$, whereas a BCD representation gives a smaller range, from 0 to $10^{n/4} - 1$. To include the sign with a binary number several strategies can be employed.
In the offset binary notation, a value of $2^n - 1$ is subtracted from the binary number to give the signed result. In the sign magnitude notation, the most significant bit (MSB) (the left-most bit) is used to represent the sign ($0 = \text{positive}$, $1 = \text{negative}$). Finally, the most practical representation from a mathematical point of view is the 2’s complement representation. In this case, a number is negated by inverting the original bits and adding 1. The 8-bit representations of the number $-27$ using each of these notations is given below.

$$-27_{10} = 0110\ 0101 \text{ (offset binary)}$$

$$= 1001\ 1011 \text{ (sign magnitude binary)}$$

$$= 1110\ 0101 \text{ (2’s complement binary)}$$

A/D conversion is facilitated using a largely self-contained circuit, the ADC. In addition to binary coding issues, important ADC parameters from a signal-processing perspective include precision, accuracy, linearity, monotonicity, and speed. The precision of an ADC is directly related to the number of bits in the digital output, but increased precision also means decreased conversion speed for a given type of ADC. Typically, 8-bit converters are used in applications where speed is more critical than precision, whereas precision applications can use as many as 16 or 20 bits. For many scientific applications, a 12-bit ADC is a good compromise, with a precision of 1 part in 4095, or 0.02%. It is important that the precision of the ADC is better than the standard deviation of the noise in the measurement, or else the dominant source of noise will be the quantization (or digitization) noise arising from rounding of the result. As the quantization noise is always fixed at a value corresponding to the least significant bit (LSB), its relative contribution increases for small values. In some cases, this problem can be addressed through autoranging, in which small signals are amplified in the analog domain prior to conversion. This is most important when the amplitude of the noise increases with the signal.

The accuracy of an ADC refers to the closeness of the converted value to the expected value based on the range of the ADC and the reference voltage. Linearity is an indication of the constancy of the proportionality of the digital output to the analog voltage over the full range of conversion, and in some cases may be more important than the actual accuracy. In a plot of the digital output versus the analog input, linearity is often specified as the maximum deviation from the straight line drawn between zero and the full scale output, or alternatively the best-fit straight line. Monotonicity is a specification that requires an increasing analog input to give an increasing digital output with no missing codes over the full range, and likewise for decreasing inputs. These specifications (accuracy, linearity, and monotonicity) are primarily a function of the ADC design and the quality of the components used.

In addition to being discrete in the measurement domain, analog signals are also discrete in the time domain, and the required conversion speed, or sampling frequency, will depend on the application. It is essential that all of the important signal characteristics in the frequency domain fall below the Nyquist frequency, $f_N$ (section 4.2). The speed of an ADC is primarily a function of the type of converter used, although it is also dependent on factors such as the number of bits and clock frequency. Although the design of new ADCs is an ongoing process driven by consumer electronics, most are variations on five basic types: (1) parallel, (2) tracking, (3) successive approximation, (4) integration, and (5) voltage-to-frequency (V/F) conversion.

The fastest and conceptually simplest ADC is the parallel ADC, often referred to as a flash converter. In this circuit, the input voltage is simultaneously compared with $2^n$ reference values and logic circuits use the closest match to produce the digital output. This brute-force approach can provide conversion speeds under 10 ns, but is not component efficient, requiring $2^n$ voltage comparators. As a consequence, this type of ADC is usually expensive and limited to 8 bits, although hybrid circuits referred to as half-flash converters, can increase the precision.

Other relatively fast circuits are based on the use of a digital-to-analog converter (DAC) to provide an analog voltage for comparison with the input voltage. The digital value passed to the DAC is systematically changed until its analog output matches as closely as possible the input voltage. At that point, the digital input to the DAC is taken to be the digital output of the ADC. Differences exist in the way that these devices change the digital values for comparison. In a tracking ADC, a simple counter is used to increment or decrement the digital value until a match is found. A block diagram for a simple tracking ADC is shown in Figure 11. Depending on the change in the voltage, the conversion time for this type of ADC could range from 0 to $2^n$ clock cycles for an $n$-bit converter. The successive approximation ADC operates on the same basic principle as the tracking ADC, but has a fixed conversion time of only $n$ clock cycles. This is accomplished by replacing the counter with circuitry that uses an efficient binary search algorithm to split the digital range in two for each comparison. Successive approximation ADCs have typical conversion times ranging from 1 to 100 $\mu$s and are among the most common converters in use.

The remaining two types of ADCs are relatively slow by comparison. Integrating ADCs are based on the use of a
The digital result is obtained by timing the period necessary for the capacitor to reach the input voltage. This basic strategy, termed a single slope integrating ADC, suffers from a dependence on accurate and stable circuit components and has been replaced by the dual slope (or even quad slope) integrating ADC. The dual slope ADC is also based on charge integration, but uses a charge–discharge cycle to cancel the effects of component variations. This type of ADC is known for its accuracy, stability, monotonicity, low cost and noise rejection characteristics and has been used in a large number of precision applications where speed is not critical. Typical conversion rates are around 10 conversions per second. In many applications, the dual slope ADC has been replaced by the V/F converter. This device simply produces a series of pulses whose frequency is proportional to the input voltage applied, with typical maximum frequencies in the range from 10 kHz to 1 MHz. To complete the conversion to a binary number, a counter is attached to the pulsed output and counted for a fixed period of time. Precision can be improved by counting for a longer period. In addition to low cost, simplicity, and good linearity, the V/F converter has the advantage that its output can be transmitted in serial over a single line, simplifying remote data acquisition. Like the integrating ADCs, however, this type of ADC is relatively slow.

Although the analyst typically has very little control over the type of A/D conversion that is used in a particular instrument, this is the first stage of all subsequent digital signal processing, so it is important to recognize the strengths and weaknesses of these devices. Further details on the design and application can be found in a number of references.\[3–5,7–8\]

### 5 Digital Filtering

#### 5.1 Introduction

Because digital filters are among the most widely used methods for signal processing in analytical chemistry, much of this article is dedicated to describing their implementation and operation. The term ‘filter’ is a reference to the similarities they share with their electronic counterparts. In both cases, the data are presented to the filter in a sequential fashion and the distinction between pure signal and noise is often made on the basis of differences in power spectra. Strictly speaking, however, a filter uses only information from the past up to and including the current point in obtaining an estimate of the current point. Although this is true for electronic filters, it does not hold for most digital filters, which use points before and after the measurement of interest to form an estimate. Thus, they may be more properly classified as smoothers or smoothing filters, but all three terms are used in the literature. The term ‘filter’ is used in a general way throughout this section, incorporating both smoothers and other types of filters.

Digital filtering can be performed either in real-time or in a post-acquisition mode. The advantage of the former is that it can be transparent to the user and optimized at the time of instrument design. Fast digital signal processors (DSPs) are available for performing common signal processing operations and can be built into the instrument itself. A disadvantage of this approach is that it removes some flexibility and may obscure some of the features of the original data. For these reasons, real-time digital filtering is often kept to a minimum and much signal processing is carried out in post-acquisition mode. Therefore, it is important to appreciate the advantages and limitations of different types of digital filters. A complete coverage of the subject of digital filters is well beyond the scope of this article. The objective here is to present some of the terminology and describe some of the digital filters commonly used in analytical chemistry. For readers seeking more information on the subject, there is abundant literature available.\[9–19\]

#### 5.2 Filter Types

In general terms, a digital filter could be defined simply as an operation that is carried out on a contiguous subset of the original signal sequence to produce an estimate of a value in the filtered signal sequence. This is illustrated in Figure 12. For conventional digital filters, the filtering operation consists of the convolution of a series of filter coefficients with the signal, but this approach is by no means universal. Digital filters are therefore classified
The most common type of digital filter employed in analytical chemistry is the nonrecursive filter, also referred to as the finite impulse response (FIR) filter because its response to an impulse (delta) function will always fall to zero at some point in time. As illustrated in Figure 13(a), nonrecursive filters use the conventional approach of convoluting a set of filter coefficients with the sequence of measurements to produce the filtered signal. If \( z_i \) represents the filtered value for measurement \( i \), it is determined mathematically by Equation (9):

\[
  z_i = \sum_{j=p}^{q} c_j y_{i+j}
\]  

where the \( c \) terms are the filter coefficients and the \( y \) terms are the original measurements. Most often, the filter coefficients are arranged symmetrically around the point to be estimated so that \( p = -q \), but this is not a requirement. Nonrecursive filters have good stability and are relatively easy to design. A simple example of a nonrecursive filter is a five-point moving average filter, which averages the five points around a central value (two on either side plus the point itself) to obtain its estimate. The coefficients in this case would be \( c_{-2} = c_{-1} = c_0 = c_1 = c_2 = 0.2 \).

Recursive filters differ from nonrecursive filters in that they make use of previously filtered values to estimate the current measurement, as shown in Figure 13(b). Mathematically, this can be represented by Equation (10),

\[
  z_i = \sum_{j=p}^{q} c_j y_{i+j} + \sum_{k=r}^{s} d_k z_{i+k}
\]

where \( z \) represents the filtered measurement, \( y \) is the unfiltered measurement, and \( c \) and \( d \) are the filter coefficients. Note that the indices \( r \) and \( s \) must be less than zero, as the filter coefficients \( d_k \) can only be applied to previously filtered values. In practice, many nonrecursive filters are designed to function in real time and so also limit the maximum value of \( q \) to be zero to make them physically realizable (i.e. they do not make use of future values). A simple example of a recursive digital filter is integration using the trapezoid rule, which gives (Equation 11):

\[
  z_i = \frac{1}{2} (y_{i-1} + y_i) + z_{i-1}
\]

This corresponds to coefficients \( c_{-1} = 0.5, c_0 = 0.5 \) and \( d_{-1} = 1 \). Recursive digital filters are also known as infinite impulse response (IIR) filters because it is possible for a single impulse input to influence filter output values indefinitely, as illustrated in this example. These filters can be used for normal smoothing operations in addition to integration, and have the advantage that they provide more efficient filters with fewer coefficients than nonrecursive filters. However, recursive filters are more difficult to design and have more complex properties than their nonrecursive counterparts, so they have not been widely used in analytical chemistry.

It is not required that digital filter coefficients remain constant throughout a sequence of measurements. In some cases, the coefficients may change in response to variations in another external input or the signal itself. These kinds of filters are called adaptive filters. Such filters are used, for example, in removing noise from audio signals using external measurements of noise characteristics. Chemical applications of this type of filter are rare, although digital processing of modulated signals, such as modulated sources in atomic absorption...
spectroscopy, could be considered to be a simple form of adaptive filtering.

Filters can also be classified according to the types of results they are intended to produce. Smoothing filters are intended to reproduce the pure signal and suppress the noise, whereas derivative filters are intended to estimate the derivative (first, second, or higher) of the pure signal. In other cases, one may wish to increase the apparent sampling frequency of a set of data, filling in points for esthetic or practical reasons (e.g., locating a peak maximum). This can be done using an interpolation filter, although care should be taken when applying such approaches. In contrast, in cases where the signal is highly oversampled, one may wish to reduce the volume of data while improving its quality by using a decimation filter.

Some types of digital filters do not follow the usual pattern of smooth convolution of a set of filter coefficients with the data, but are considered digital filters nevertheless. In boxcar averaging, for example, the signal is divided into subsets of \( n \) measurements which are averaged to produce a single result, as shown in Figure 14. As this reduces the total number of points, it is one type of decimation filter. Another rarely used but very useful filter is the median filter. Although this filter should be used with care because of its nonlinear transformation of the data, it is particularly effective at removing spikes or outliers from a measurement sequence. These outliers may arise, for example, from cosmic rays striking a photodetector or bubbles passing through a detector flow-cell. The median filter works by sorting the data within a window of length \( n \) and choosing the median value as the filtered estimate, thus automatically eliminating outliers unless they occur in clusters. An example of the application of the median filter is shown in Figure 15.

Because of their dominance in chemical applications the main emphasis of this article is on nonrecursive digital filters, particularly polynomial least-squares filters, although some discussion of Kalman filters is also presented.

5.3 Polynomial Least-squares Smoothing Filters

By far the most widely applied digital filter in analytical chemistry is the polynomial least-squares smoothing filter. These filters are more commonly known to analytical chemists as SG filters, a reference to their introduction into the analytical chemistry literature by Savitzky and Golay in 1964.\(^1\) Although these filters were known in the field of signal processing prior to this, the SG paper made their utility known to chemists at a time when the digital acquisition of signals was becoming more commonplace. In addition, the paper presented tables of precalculated coefficients for different types of filters. At the time, computational efficiency was poor, so the authors presented the coefficients as integers with a normalization factor rather than as a series of floating point numbers.

Among the advantages of the SG filters are their simplicity and versatility. Application of these filters assumes that a local region of the data set (i.e., the filter window) can be fit to a low-order polynomial, and the central point within that window is estimated by performing such a fit. This is illustrated in Figure 16 for first- and second-order polynomials. Fitting the data in this way should model the correlations in the pure signal while reducing the influence of random noise fluctuations. Furthermore, when the measurements are evenly spaced in the time domain, the fitted estimate of the central point can be obtained simply by multiplying the points in the window by a set of precalculated coefficients, thus making the fit equivalent to a nonrecursive digital filter.

The original tables published by SG had a number of errors that were later corrected in the literature,\(^2\) but it is now just as simple to calculate the coefficients for a given application, so the tables are seldom used. To illustrate how this is done, consider the design of a second-order polynomial smoothing filter using a five-point window.

---

**Figure 14** Illustration of boxcar averaging.

**Figure 15** A noisy peak (upper curve) before and (lower curve) after filtering with a median filter. Note the removal of spikes.
The model to be fit is Equation (12):

\[ y = b_0 + b_1 x + b_2 x^2 \]  \hspace{1cm} (12)

Equation (13) is the equivalent matrix form:

\[
\begin{align*}
&y_1 = 1 \ x_1 \ x_1^2 \\
&y_2 = 1 \ x_2 \ x_2^2 \ b_0 \\
&y_3 = 1 \ x_3 \ x_3^2 \ b_1 \\
&y_4 = 1 \ x_4 \ x_4^2 \ b_2 \\
&y_5 = 1 \ x_5 \ x_5^2 \\
\end{align*}
\]  \hspace{1cm} (13)

which can be expressed as (Equation 14):

\[ y = Xb \]  \hspace{1cm} (14)

In these expressions, \( x \) represents the time or other ordinal variable, while \( X \) is the matrix containing the basis functions for the polynomial fit. It is important to note that the fitted values obtained for \( y \) are independent of the scale of \( x \) and, if the time interval between each measurement is equal (as is usually the case), we can arbitrarily set \( x = [-2, -1, 1, 2] \), giving Equation (15):

\[
\begin{pmatrix}
1 & -2 & 4 \\
1 & -1 & 1 \\
1 & 0 & 0 \\
1 & 1 & 1 \\
1 & 2 & 4 \\
\end{pmatrix}
\]  \hspace{1cm} (15)

The least-squares solution for the vector of regression coefficients, \( b \), is well known from linear algebra to be (Equation 16):

\[ b = (X^T X)^{-1} X^T y = Ay \]  \hspace{1cm} (16)

The matrix \( A \) is a \( 3 \times 5 \) matrix which can be regarded as being composed of three row vectors, \( a_1 \), \( a_2 \), and \( a_3 \); as in Equation (17):

\[ A = \begin{pmatrix}
 a_{11} & a_{12} & a_{13} & a_{14} & a_{15} \\
 a_{21} & a_{22} & a_{23} & a_{24} & a_{25} \\
 a_{31} & a_{32} & a_{33} & a_{34} & a_{35}
\end{pmatrix} \leftrightarrow a_1 \rightarrow (17) \]

Note that the intercept coefficient for the fit, \( b_0 \), is obtained from Equation (18),

\[ b_0 = a_1 y = a_11 y_1 + a_12 y_2 + \cdots + a_15 y_5 \]  \hspace{1cm} (18)

Also note that, as \( x = 0 \) for the central point in the five point sequence, Equation (19) holds:

\[ \hat{y}_3 = b_0 + b_1 (0) + b_2 (0)^2 = b_0 = a_1 y \]  \hspace{1cm} (19)

Therefore, because of the way the problem has been set-up, the estimate of the central point in the sequence is obtained simply by multiplying each measurement by the corresponding element in \( a_1 \). In other words, the digital filter coefficients are simply the first row of the matrix \( (X^T)^{-1}X^T \), i.e. \( c = a_1 \).

The above reasoning holds for polynomial smoothing filters of any length and any order. All that is required to determine the filter coefficients is to set up the matrix of basis functions, \( X \), perform the calculation in Equation (16) using a spreadsheet or other software, and extract the first row of the resulting matrix. Polynomial smoothing filters are convenient for improving the appearance and SNR of many signals and have the added advantage over electronic filters that different types of filters can be applied after the signal has been recorded.

One of the drawbacks of polynomial smoothing filters is sometimes referred to as the edge effect. As the filters are designed to obtain an estimate of the central point in a window, there will be points at the beginning and end of a measurement vector that cannot be estimated with the symmetric filter. For example, with the five-point filter described above, two points could not be filtered at each end of the data sequence. Several options are available to deal with this problem. The simplest is either to drop these points from the data set, or leave them in the data set unfiltered. Another possibility, if only baseline data occurs at the limits of the measurement vector, is to use the points at one end of the data set to filter those at the other. For example, to estimate \( y_1 \) with the five-point filter, we could use the sequence \( (y_{n-2}, y_{n-1}, y_1, y_2, y_3) \). Finally, we could employ what are sometimes referred to as initial point filters or extended sliding window filters,\(^{(21,22)}\) designed to estimate values other than the central point of a sequence. The coefficients for these filters are easily obtained by simply shifting the \( X \) matrix accordingly. For example, to obtain coefficients to estimate the first point of a five point sequence with a

---

**Figure 16** Illustration of polynomial smoothing as a least-squares fitting procedure.
second-order smooth, we would use Equation (20):
\[
\begin{bmatrix}
1 & 0 & 0 \\
1 & 1 & 1 \\
1 & 2 & 4 \\
1 & 3 & 9 \\
1 & 4 & 16 \\
\end{bmatrix}
\]  
(20)

All other aspects of the problem are the same. Although this is an elegant way to solve the problem, it requires several sets of filter coefficients to handle the points at the edges of the data and the noise rejection and signal distortion characteristics of these filters are not identical to the symmetric filters.\(^{(23)}\)

The selection of smoothing filter parameters (order, number of points) for a given application is often a matter of trial and error and intuition. Obviously, one would like to obtain the maximum noise reduction with the minimum amount of distortion. Although the best noise reduction occurs with wider filters (more points), wider filters also limit the ability of the chosen function to obtain a good local model for a changing signal. In general, noise rejection improves and signal distortion increases as the width of the signal increases and the order of the filter decreases. It should be noted, however, that as a consequence of the mathematics, smoothing filters for orders 0 and 1 are identical, as are those for orders 2 and 3, and so on. To determine the amount of noise reduction a filter will provide, there is a very simple relationship (Equation 21):

\[
\frac{\sigma_{\text{filtered}}^2}{\sigma_{\text{unfiltered}}^2} = \sum_{j=p}^{q} c_j^2
\]  
(21)

Thus the ratio of the variance of the noise in the filtered signal to that in the unfiltered signal is simply the sum of the squared filter coefficients. This equation applies to any type of nonrecursive digital filter, but is only valid in cases where the signal exhibits white noise.

Although Equation (21) is useful for describing the amount of noise reduction, it provides no information about the extent of signal distortion. To this end, it is often more useful to examine the response of a digital filter in the frequency domain in much the same way as an electronic filter. For a symmetric smoothing filter, the frequency response is given by Equation (22),

\[
H(f) = \sum_{k=-m}^{m} c_k \cos \left( \frac{k\pi f}{f_N} \right)
\]  
(22)

where \(H(f)\) is the amplitude gain of the filter at frequency \(f\), \(c_k\) represents the filter coefficients, and \(f_N\) is the Nyquist frequency. Note that this does not apply to unsymmetric smoothing filters, such as the initial point filters, because these filters also involve a phase shift, but alternative expressions are available.\(^{(23)}\) Figure 17 shows the frequency response for an 11-point quadratic smoothing filter, plotted as a function of \(f/f_N\) to make it universal. As expected, the amplitude gain is unity at low frequencies and drops off at higher frequencies. Unlike simple electronic filters, however, the gain of these filters does not smoothly approach zero, but instead oscillates around a number of nodes that are related to the size and order of the filter. Furthermore, if the frequency response were plotted beyond the Nyquist frequency, the function would simply reflect itself as signals were aliased to lower frequencies, reaching a gain of unity once again at the sampling frequency. If one has some idea of the amplitude spectrum of the signal to be filtered, plots such as Figure 17 can be very useful in assessing the degree of signal distortion that will result from filter application. The amount of noise rejected can be also ascertained from the ratio of the area under the NPS before and after multiplication by the filter frequency response. Clearly, this type of filter will be effective when white noise is present, but will be less effective for \(1/f\) (drift) noise, as the noise exists predominantly at low frequencies. It should also be noted that even if white noise was present before filtering, measurement noise will become correlated after filtering.

Of course, whenever a digital filter is applied to experimental data, there will be changes in the shape of the signal. In certain cases where parameters of the signal such as peak height, area or width are important in themselves, consideration must be given to the consequences of applying a digital filter. Generally, for signals which exhibit the same shape, the effects in the time domain (e.g. width at half-maximum) will be the same, whereas effects on the amplitude (e.g. peak height/area) will be linear with the magnitude of...
the signal. The reader is referred to a useful, although somewhat empirical, study by Enke and Nieman for more details on these effects.\(^{16}\)

### 5.4 Derivative Filters

The numerical differentiation of signals with respect to time (or other ordinal variable) is a common practice in analytical chemistry. This procedure can be used, for example, to locate the position of a peak maximum, to determine the end-point of a titration, or to highlight poorly defined features in a signal sequence (e.g. the shoulder on a peak). These can be regarded as qualitative applications in the sense that one is looking for the location of specific points in the signal derivative (e.g. the maximum or zero values) but not using the derivative sequence for further calculations. Quantitative applications, in which the differentiated signal is used for purposes such as calibration, have become more common in recent years. Because the derivative of a function is unaffected by the addition of a constant, differentiation proves valuable for methods which exhibit a baseline shift (offset) between samples. Likewise, if sample measurements are plagued with a baseline that changes linearly with the ordinal variable (drift), calculation of the second derivative can solve the problem.

One serious problem with signal differentiation is the selective amplification of high-frequency noise. Because the derivative of a signal is, by definition, its rate of change, the more rapidly varying components of a signal, including noise, are amplified to a greater extent than the more slowly changing features typically associated with the pure signal. Because of this, derivative filters (first, second or higher) are most useful for signals which exhibit relatively small amounts of high-frequency noise compared to the low-frequency contributions, i.e. cases where \(1/f\) or drift noise dominates. A classic example of this is near-infrared (NIR) spectroscopy, where second derivatives are routinely calculated prior to quantitative analysis. Although NIR measurements are widely characterized in the literature as having very high SNRs, these measurements suffer from serious noise problems in the form of baseline offset and drift, but traditional SNR calculations normally do not incorporate these components. Fortunately, the characteristics of NIR spectra make them almost ideal benefactors of derivative filtering.

The noise amplification characteristics of derivative filters can be better understood by examining the transfer function in the frequency domain. As shown in Figure 17, the gain of a smoothing filter is typically unity at low frequencies and falls off at high frequencies. In contrast, Figure 18 shows that the gain of a true derivative filter increases linearly with frequency. This can be easily confirmed by recognizing that (Equation 23),

\[
\frac{d(sin wt)}{dt} = w \cos wt
\]  

where \(w = 2\pi f\) is the angular frequency. As a signal in the time domain can be represented as the sum of a series of sines and cosines (section 6.2) it is clear the calculation of the derivative amplifies a signal component by a factor of \(w\) and also gives rise to a 90° phase shift. The consequence of this is that the excessive amplification of high-frequency noise components generally makes the calculation of the true derivative for practical measurements useless (and is the reason why the term ‘true’ is used instead of ‘ideal’). In practice, most derivative filters implicitly combine the derivative calculation with a low-pass filter to reduce the contribution of high frequency components.

The simplest method for calculating a signal derivative, and one which can be described as a simple digital filter, is the difference operator, defined by Equation (24),

\[
\hat{y}'_i = \frac{y_{i+1} - y_i}{\Delta t}
\]  

where \(\hat{y}'_i\) represents the estimate of the derivative of the function at point \(i\), and \(\Delta t\) is the sampling interval. The transfer function for this type of filter is shown in Figure 18. It is clear that the frequency response for a simple difference operator matches that of the true derivative closely except at very high frequencies. This type of filter provides no low-pass filtering, however.

An alternative way of calculating derivatives is to use a slight modification of the polynomial least-squares filters described in section 5.2. If we carry out the least-squares fit in the same manner as the previous example for a five-point quadratic model, the estimate of the derivative for the central point is given by
Equation (25),
\[
\frac{d}{dx}(b_0 + b_1x_0 + b_2x_0^2) = b_1 + 2b_2 = b_1 + 2b_2(0) = b_1
\]
Therefore, the derivative estimate of the central point is simply the first-order coefficient of the fit. In a manner analogous to Equation (18), this is obtained by simply multiplying the second row of the \( A \) matrix by the windowed measurement vector \( y \). This means that the coefficients of the derivative filter are given by the second row of \( A \) (\( c = a_2 \)) as opposed to the first row of \( A \) for the smoothing filter. Likewise, the filter coefficients for the second derivative are given by the third row of \( A \), and so on. It is clear then, that there is a simple, common path to the calculation of polynomial filters of various types.

A number of characteristics of derivative filters calculated in this way should be noted. First, unlike smoothing filters, the calculation of numerically correct derivatives requires consideration of the sampling interval. The adjusted coefficients necessary to obtain the correct scale are given by Equation (26),
\[
c_{\text{adjusted}} = \frac{c_{\text{original}}(\Delta t)^p}{p!}
\]
where \( p \) is the order of the derivative. In many cases, this scaling is ignored, because it is only the relative changes in the derivative that are important. A second characteristic of these derivative filters that should be apparent from the mathematics is that the determination of coefficients for a \( p \)th order derivative requires at least a \( p \)th order polynomial. Also, as with smoothing filters, there is a duplication of coefficients for adjacent polynomial orders, although the pairing shifts with each higher derivative. For example, for the first derivative, the filter coefficients for the linear and quadratic polynomials are the same, whereas the quadratic and cubic coefficients are the same for the second derivative.

The polynomial filters described here are symmetric in the sense that there are an equal number of coefficients on either side of the central point (in fact, a first-derivative filter is better described as antisymmetric, as \( c_{-j} = -c_j \)). As with smoothing filters, it is possible to develop derivative filters for the edges of a window, but the usual precautions regarding the quality of estimates apply. For symmetric first-derivative filters, the frequency response is given by,
\[
H(f) = \sum_{k=-m}^{m} c_k \sin \left( \frac{k\pi f}{f_N} \right)
\]
Figure 19 Result of the application of various types of derivative filters to a noisy peak, shown above: (a) difference operator, (b) 3-point linear derivative filter, (c) 11-point linear derivative filter.

Equation (27) is a slight modification of Equation (22), where the substitution of sine for cosine results from the

90° phase shift brought about by the derivative filter. The frequency responses for 3-point and 11-point first-order derivative filters are shown in Figure 18 for comparison with the true derivative and difference operator. Note that although the transfer functions for the polynomial filters match the true derivative at low frequencies, there is significant attenuation at high frequencies due to the low-pass filtering. The effects of this low-pass filtering are clearly seen in Figure 19, which shows the application of three types of derivative filters to a noisy signal. Because of the effect of high-frequency noise on derivative filter response, it is a common practice by some to first apply a smoothing filter to the data, but Figures 18 and 19 demonstrate that if the derivative filter is properly designed, this practice is redundant.

5.5 Kalman Filters

The Kalman filter is a recursive linear least-squares estimator with the capability of estimating the parameters associated with a system model in real time.\(^{17–19}\) It is not so much a filter in the conventional sense as it is a means for carrying out linear least-squares in a recursive fashion. The estimates it provides are not the smoothed measurements, but rather the parameters associated with the linear model, or the state parameters. These parameters are sometimes considered to represent a state vector in an \( n \)-dimensional state space (\( n \) = number of parameters). Once the state parameters have been estimated, it is possible to generate a smooth curve for
the measurements from the model, but this is usually a secondary objective.

A simple example of recursive estimation in a manner similar to the Kalman filter is the calculation of a mean from a series of measurements as the measurements are being acquired. It is usual to start with an estimate of the mean equal to the first measurement, i.e. \( \hat{m}_1 = x_1 \). Once a second measurement was acquired, the estimate could be improved by using \( \hat{m}_2 = 1/2\hat{m}_1 + 1/2x_2 \). In general, after the \( i \)th measurement, Equation (28) would hold:

\[
\hat{m}_i = \frac{i-1}{i}\hat{m}_{i-1} + \frac{1}{i}x_i
\]  

(28)

As each new measurement is assimilated into the estimation, the quality of the parameter estimate improves. It is apparent that Equation (28) has the form of a recursive filter whose coefficients are changing with each measurement. An advantage of recursive estimation is that continuous updates of the parameter(s) of interest are obtained with each new measurement. Although this could also be done in batch mode, the recursive formulation is computationally more efficient.

The general model which is covered by the Kalman filter can be described by Equations (29) and (30):

\[
x_{k+1} = F_kx_k + w_k
\]  

(29)

\[
z_k = H_kx_k + v_k
\]  

(30)

In these equations, \( x_k \) represents the \( n \times 1 \) vector of parameters to be estimated (the state vector) at measurement interval \( k \) and \( z_k \) represents the \( m \times 1 \) vector of measurements at interval \( k \). The first equation describes how the state vector is expected to change from one measurement interval to the next and contains both systematic and stochastic terms. The \( n \times n \) state transition matrix, \( F \), describes the systematic linear transformation, whereas the vector of random variables, \( w \), represents the stochastic change. Each element of \( w \) is assumed to be derived from a zero-mean white-noise sequence and \( w \) is characterized by an \( n \times n \) covariance matrix \( Q \).

Equation (30) describes how the state parameters are translated into a measurement or observation vector. The linear relationship is described by the \( m \times n \) observation matrix, \( H \). There is also a random noise component assumed for the observations, represented by the vector \( v \). The elements of this vector are also assumed to comprise a white-noise sequence and the covariance of noise in the measurement vector is described by the \( m \times m \) covariance matrix, \( R \).

The basic algorithm for the Kalman filter is shown in Figure 20, although several variants exist. The application of this algorithm is best described through a simple example. Suppose, for the purposes of illustration, we are using an absorption spectrometer to monitor a reaction in which two absorbing species, A and B, are reacting independently to form nonabsorbing products by first-order kinetics. The defining Equation (31) is:

\[
z(t) = A(t) = C Ae^{-k_A t} + C B e^{-k_B t} + v(t)
\]  

(31)

where \( A(t) \) is the absorbance at time \( t \), \( C_A \) and \( C_B \) represent the initial concentrations of the two species, \( \varepsilon_A \) and \( \varepsilon_B \) are their molar absorptivities, and \( k_A \) and \( k_B \) are their first-order decay constants. Assuming that all quantities are known except the initial concentrations which are to be estimated, this is a linear problem (Equations 32):

\[
x(t) = \begin{bmatrix} C_A \\ C_B \end{bmatrix} ; \quad H(t) = [\varepsilon_A e^{-k_A t} \quad \varepsilon_B e^{-k_B t}]
\]  

(32)

A simulated data set was generated using \( C_A = 0.2 \text{ mM, } C_B = 0.5 \text{ mM, } \varepsilon_A = 1000 \text{ M}^{-1} \text{ cm}^{-1}, \varepsilon_B = 1500 \text{ M}^{-1} \text{ cm}^{-1}, k_A = 0.1 \text{ s}^{-1}, k_B = 0.3 \text{ s}^{-1} \), and a noise level of 0.02 absorbance units (AU). These data, showing the measured points and the curve with no error, are presented in Figure 21(a). The objective of the Kalman filter is to provide estimates of \( C_A \) and \( C_B \) as each new measurement is made.

To initiate the Kalman filter prior to step 1, we need an estimate of the state parameters and the error covariance matrix, \( P \), describing the uncertainty in those parameters. Assuming we have no prior knowledge, we use Equations (33):

\[
x_I = \begin{bmatrix} 0 \\ 0 \end{bmatrix} ; \quad P_I = \begin{bmatrix} 10^{10} & 0 \\ 0 & 10^{10} \end{bmatrix}
\]  

(33)

The superscript ‘−’ indicates that these are the estimates before we have assimilated the first measurement. As we have no prior knowledge of the parameters, the diagonal

---

**Figure 20** Basic algorithm for the Kalman filter.
elements (variances) of the covariance matrix are set to very large values. In order to estimate the Kalman gain, \( K \), in step 1, the observation matrix, \( H \), can be calculated from Equation (32). As the measurement, \( z \), is a scalar in this case, the measurement error covariance matrix, \( R \), is simply equal to the variance of the measurements. Thus, at \( t = 0.5 \) s, Equations (34) hold:

\[
H_1 = [951.2 \quad 1291.1]; \quad R_1 = (0.02)^2 = 0.0004 \quad (34)
\]

With these values, the \( n \times 1 \) Kalman gain vector for this iteration is Equation (35):

\[
K_1 = \begin{bmatrix} 3.699 \times 10^{-4} \\ 5.020 \times 10^{-4} \end{bmatrix} \quad (35)
\]

In step 2 of the algorithm, the difference between the actual observation, \( z_k \), and the observation predicted by the current state parameters, \( H_1 x_k \), is calculated. This difference is sometimes called the innovation and is like an ordinary residual except that it is calculated using the current rather than the final parameter estimates. The Kalman gain vector, \( K \), determines how much the innovation is weighted in updating the state parameter estimates. It is also used in the third step of the algorithm to update the error parameter error covariance matrix, \( P \), following integration of the new measurement. Using the first observation of 0.846 AU gives Equations (36):

\[
x_1 = \begin{bmatrix} 0.313 \\ 0.425 \end{bmatrix} \times 10^{-3}; \quad P_1 = \begin{bmatrix} 6.5 & -4.8 \\ -4.8 & 3.5 \end{bmatrix} \times 10^9 \quad (36)
\]

Note that because only one measurement has been processed and there are two parameters to be estimated, neither \( x \) nor \( P \) can be regarded as reliable at this point.

In step 4, the state vector and its covariance matrix are projected ahead to the next measurement interval. This requires a knowledge of \( F \) and \( Q \), which are trivial in this example. As the state parameters here are static (i.e. \( x \neq f(t) \)), the state transition matrix, \( F \), is simply the identity matrix. This would not be the case, for example, if the state parameters were the concentrations at time \( t \), rather than the initial concentrations, but the modifications to \( H \) and \( F \) would be straightforward in that case. Likewise, we are assuming no random variation in the initial concentrations, so the state vector covariance matrix, \( Q \), is equal to zeros. The role of \( Q \) in a more complex application is to allow for random variation in the state parameters over time. As an example, suppose that instead of absorbance, we were measuring total pressure in a gas phase reaction which was subject to random temperature fluctuations between measurements. This would effectively change the initial pressures we were trying to estimate.

The iterations of the Kalman filter continue in this way until all of the measurements have been processed. For the example presented here, Figure 21(b) shows the concentration estimates as a function of time with the final estimates:

\[
C_A = 0.186 \pm 0.019 \text{ mM} \\
C_B = 0.522 \pm 0.023 \text{ mM}
\]

The uncertainties are the standard deviations of the parameters from \( P \). Note that these converge to values close to the true concentrations. It should also be noted that these are essentially the same estimates that would have been obtained by linear least-squares implemented in batch mode.

Although Kalman first introduced this filter in 1960,\(^{24}\) applications in chemistry were not abundant until the late 1970s and early 1980s. However, many of these applications employed the Kalman filter mainly as a recursive implementation of simple least-squares, such as the example above, and did not exploit its full capabilities. For instance, given spectra of mixture components, the Kalman filter can be used to estimate component concentrations as a spectrum was being scanned. Although this offered certain advantages such as speed and the ability to terminate an experiment.
when the desired precision was achieved, developments in instrumental and computational efficiency have made these benefits less significant. The potential exists for more effective utilization of the algorithm, however.

At least two modifications of the basic Kalman filter have also appeared in the analytical chemistry literature. The extended Kalman filter\(^{25}\) has been used to model nonlinear systems (e.g. the estimation of rate constants in the example above) through a linearization of the equations but, like most nonlinear methods, convergence can be slow and subject to initial estimates. Often, several passes are needed, defeating the advantages of recursion. A more successful application has been the adaptive Kalman filter,\(^{26}\) which examines the innovations sequence to detect model errors and effectively turns the filter off in those regions by using an inflated measurement variance estimate. This allows the filter to be applied in situations where strict adherence to the model is not a certainty.

5.6 Other Filters

This section has only scratched the surface of digital filter design, focusing on those filters which are most commonly implemented in analytical chemistry. The reader should be aware that nonrecursive filters with more desirable transfer characteristics, such as a flatter stop band, can be designed with relatively little additional effort, and is referred to appropriate texts on the subject.\(^{9-11}\) Even more flexibility can be achieved with recursive filters, with characteristics analogous to the Butterworth and Chebyshev designs described earlier for analog signal processing. The popularity of polynomial least-squares filters appears to be a consequence of their intuitive simplicity and the fact that, although not necessarily optimal, they are sufficient for many applications.

The subject of optimal filtering is revisited in the next section with the Weiner filter in the Fourier domain. In terms of optimal filtering in the time domain, however, one additional filter, the matched filter, deserves mention because it often appears in the analytical literature. With a matched filter, the filter coefficients are obtained simply by normalizing the shape of the pure signal. This is illustrated in Figure 22 with a noisy Gaussian. For white noise, the matched filter is optimal in the sense that it produces the largest SNR, interpreted as the maximum value divided by the baseline noise. Unfortunately, it requires an advance knowledge of the signal shape and has the undesirable consequence of broadening the peak. The optimality of the matched filter derives from its connection to regression. This connection, as well as the relationship between Kalman filtering and regression, has been described by Erickson et al.\(^{27}\)

6 DOMAIN TRANSFORMATIONS

6.1 Introduction

In the context of signal processing, a domain transformation can be defined as a mathematical or physical process that converts a sequence of measurements into an alternative representation which retains all of the information in the original sequence. A domain transformation is distinguished from a simple domain conversion, such as scaling or current-to-voltage conversion, in that it involves a redefinition of the ordinal variable. As such, the procedures are comparatively complex.

There are two principal reasons why domain transformations are used in chemistry. The first is so that information can be represented in a form commonly used for interpretation. A familiar example is Fourier transform infrared (FTIR) spectroscopy in which the signal, collected by means of an interferometer in the time domain, must undergo a transformation in order to represent it as the familiar plot of transmittance versus wavenumber. The second use of domain transformations is to allow certain operations to be carried out on signals with greater ease. As the objective of signal processing is to separate the pure signal from the noise, transformations which provide a better distinction between these two elements of the signal are useful.

Although there are a large number of possible domain transformations that can be employed, this section will focus on three which have been particularly useful in analytical chemistry: the FT, the WT and the HT.

6.2 Fourier Transforms

Without a doubt, the most widely encountered domain transformation in chemistry is the FT. In addition to being
a useful stand-alone signal processing tool, the FT has become an integral part of many instrumental methods (FTIR, FT/NMR (nuclear magnetic resonance), FTRS (Fourier transform Raman Spectroscopy) and FTMS (Fourier transform mass spectrometry)). Although the FT can be applied to both continuous and discretely sampled functions, it is the latter which dominates instrumental applications and will be the focus of this section. The section begins with a basic description and simple illustration of the principles of the FT and concludes with some examples of its application to signal processing. Abundant supplementary information can be found in the literature. \(^{(13,14,28-34)}\)

The fundamental principle behind the discrete FT is that any signal sampled at equal intervals in the time domain can have the sampled points reproduced by the addition of a finite number of sinusoids at defined frequency intervals with variable amplitude and phase. This is illustrated in Figure 23 with the simple example of a sampled square wave. Figure 23(a) shows the square wave with the sampled points and the reconstruction using the combination of sinusoids. Although the reconstruction does not match the square wave exactly, it does reproduce the sampled points exactly, which is its only requirement. If the square wave were sampled more frequently, a larger number of sinusoids would be required for reconstruction. Figure 23(b) shows the individual sinusoids added to give the reconstruction, including the DC (direct current) offset (sine wave with frequency of zero).

</table>

Although two cycles of the square wave are shown in Figure 23 for clarity, the FT is based on a single cycle of 10 points. The reconstruction of the sampled points from the sinusoid terms can be represented as

\[
h(t) = \sum_{n=0}^{N/2} C_n \cos \left( \frac{2\pi nf_s t}{N} + \phi_n \right) \tag{37}\n\]

In Equation (37), \(h(t)\) represents the reconstructed signal at time \(t\), \(f_s\) is the sampling frequency, \(N\) is the number of points sampled, and \(C_n\) and \(\phi_n\) represent the amplitude and phase of the \(n\)th sinusoid, which has a frequency of \(f_s = (n/N)f_s\). Note that an equivalent representation using sines rather than cosines could have been written simply by adding 90° to \(\phi_n\), but a cosine expansion is more consistent with FT calculations. For the example in Figure 23, the coefficients \(C_n\) and phase angles \(\phi_n\) are given in Table 2 (a sampling interval of 1 s was assumed). Several points should be noted here. First, two sets of amplitudes and angles are given in the table to illustrate an ambiguity in this type of representation – the same result can be obtained by changing the sign of any of the coefficients and shifting the corresponding phase angle by 180°. A second important point is that, whichever set of values is used, there are 12 parameters provided to describe the sinusoids (6 amplitudes and 6 phase angles). Given that we are representing 10 points in the time domain, it would seem that an excessive number of parameters is needed to describe the signal in the Fourier (frequency) domain. However, this is misleading, because the mathematical restrictions can always fix the phase angles for 0 Hz and the Nyquist frequency (0.5 Hz in this case) to be 0°. Therefore, an equal number of values can be used to represent the signal in both domains. Finally, it should be noted that the periodic nature of the sinusoidal basis functions will give rise to a periodic reconstruction even if the original signal is not periodic. This does not mean that nonperiodic signals cannot be transformed, but it should be kept in mind that the FT will treat them as if they are periodic. Discontinuities in amplitude between the beginning and the end of a signal sequence will be reflected in the high frequency components of the FT.

The ambiguity which arose in the amplitude/phase representation of the FT can be resolved by exploiting...
the fact that a phase shifted sinusoid can be represented as a linear combination of sine and cosine terms. Therefore, an equivalent form of Equation (37) is Equation (38):

\[ h(t) = \sum_{n=0}^{N/2} A_n \cos \left( \frac{2\pi n f_t}{N} \right) + B_n \sin \left( \frac{2\pi n f_t}{N} \right) \]  

(38)

For the square wave example, the coefficients \( A_n \) and \( B_n \) are also given in Table 2. Although the phase angle has been removed, the same number of parameters as before is required to describe the signal, but there is no ambiguity. The basic objective of the FT is to obtain the coefficients \( A_n \) and \( B_n \). Mathematically, this is done by separating the sine and cosine terms through complex arithmetic, recalling Euler’s relationship (Equation 39):

\[ e^{i\theta} = \cos \theta - i \sin \theta \]  

(39)

where \( i = \sqrt{-1} \).

The discrete FT is mathematically defined as follows. Given a series of \( N \) measurements in the time domain, \( h_k \), where \( k = 0 \ldots N - 1 \), the \( N \) complex coefficients of the FT, \( H_n \), where \( n = 0 \ldots N - 1 \), are given by Equation (40):

\[ H_n = \sum_{k=0}^{N-1} h_k e^{2 \pi i k n / N} \]  

(40)

This calculation results in \( N \) real coefficients and \( N \) imaginary coefficients which are related to the coefficients \( A_n \) and \( B_n \) in Equation (38). However, the total number of coefficients here is \( 2N \), whereas the total number in Equation (38) was \( N + 2 \), which suggests that there is some redundancy. This arises because the FT produces coefficients at both positive and negative frequencies. This is illustrated in Figure 24 which shows the actual FT of the sampled square wave in Figure 23. Both the real and imaginary parts of the FT are shown and the labels on the x axis indicate the correspondence between the coefficient number, \( n \), and the frequency. Note that 0 Hz (DC) and the Nyquist frequency (\( f_N \)) are represented only once in the mapping, whereas both positive and negative values are shown for other frequencies. Furthermore, there is a symmetry between the positive and negative frequencies such that Equation (41) holds:

\[ H(-f) = H(f)^* \]  

(41)

where the asterisk indicates the complex conjugate. This symmetry arises from the fact that \( h_k \) is a real function and has no imaginary components.

The representation of the real and imaginary parts of the FT as shown in Figure 24 is an unambiguous presentation of the transform and is the one used in calculations, but it is not normally the one shown in practice. Typically, figures show an amplitude spectrum or a power spectrum and (less frequently) a phase spectrum. Unfortunately, there is a great variability in the scaling and presentation of these spectra, so caution needs to be employed in their interpretation. One way to calculate the amplitude spectrum is to calculate the modulus of \( H \) directly (Equation 42):

\[ \text{Amp}(f) = \sqrt{ \text{real}(H(f))^2 + \text{imag}(H(f))^2 } \]

\[ = \sqrt{ H(f)H(f)^* } = |H(f)| \]  

(42)

The results of this calculation for the square wave example are shown in Figure 25(a), where the frequency values have also been properly ordered. Because of the symmetry of the figure for real data, the amplitude spectrum is often represented as simply the right-hand side, excluding negative frequencies. If this were done here, it is clear that the amplitude spectrum would not be consistent with the values given in Table 2. There are three reasons for this. First, the amplitude spectrum calculated in this way will always give positive values because of the ambiguity in the sign of the square root. Second, there is a scaling factor of \( 1/N \) needed to go between Figure 25(a) and Table 2. This scaling factor normally appears in the inverse Fourier transform (IFT), defined by Equation (43):

\[ h_k = \frac{1}{N} \sum_{n=0}^{N-1} H_n e^{2 \pi i k n / N} \]  

(43)

(Note that the IFT is essentially the same as the forward FT except for the sign change and the scaling factor.)

**Figure 24** FT of the sampled square wave in Figure 23(a) (one cycle of 10 points only) showing the real and imaginary components and the mapping of points to the frequency domain.
Finally, in order to arrive at an amplitude consistent with Table 2, it is necessary to combine positive and negative frequencies (except for DC and \( f_N \)). Thus an alternative definition of the amplitude spectrum (nonnegative frequencies only) is Equations (44):

\[
\begin{align*}
\text{Amp}(0) &= \frac{1}{N} |H(0)| \\
\text{Amp}(f) &= \frac{1}{N} (|H(f)| + |H(-f)|) = \frac{2}{N} |H(f)| \\
\text{Amp}(f_N) &= \frac{1}{N} |H(f_N)|
\end{align*}
\]

(Equation 44)

This representation of the amplitude spectrum is shown in Figure 25(b) and, except for the signs, is consistent with the data in Table 2.

The power spectrum (or power spectral density function) is often used in place of the amplitude spectrum. As its calculation involves squaring the amplitudes, the same scaling inconsistencies exist here as for the amplitudes, so care should be taken. The power of the signal in the two domains is related through Parseval’s theorem (Equation 45):

\[
\sum_{k=0}^{N-1} |h_k|^2 = \frac{1}{N} \sum_{n=0}^{N-1} |H_n|^2
\]

One method to arrive at a valid power spectrum is to use a set of equations similar to those given in Equation (44) for the amplitude, replacing amplitude with power by squaring each of the modulus terms and each \( N \). This gives the power spectrum in Figure 25(c). It can be verified that the sum of the elements is equal to 0.5, which is equal to the mean squared value of the signal in the time domain. There are other aspects to the calculation of power spectra, such as windowing methods to prevent leakage among frequencies and improve the quality of the spectral estimation, but these will not be described here.

Although there are some variations in the manner of calculation of amplitude and power spectra, these are not especially serious when the FT is used for descriptive purposes. The phase spectrum, which plots the phase angle as a function of frequency, is less useful than the amplitude spectrum in most instances.
The phase spectrum for the current example is shown in Figure 25(d). As the negative frequencies contain redundant information by symmetry, only the positive half of the phase spectrum is shown. The phase angles are calculated from Equation (46):

\[ \phi(f) = \tan^{-1}\left( \frac{\text{imag}(H(f))}{\text{real}(H(f))} \right) = \text{arg}(H(f)) \]  

(46)

As in the amplitude calculation, this equation will have an ambiguity due to the fact that the angle calculated will always be between \(-90^\circ\) and \(+90^\circ\). Table 2 indicates that, in this case, positive amplitudes should produce phase angles outside this range, but this is clearly not reflected in the phase spectrum. Therefore, although the amplitude/power and phase spectra are the most common descriptive forms of the FT, the indeterminacy of the resultant parameters means that they cannot actually be used to regenerate the original signal in most cases. It should also be noted that Equation (46) involves the ratio of two numbers and this can cause problems in the phase angle calculation when both terms are very close to zero, since round-off error leads to an arbitrary phase angle. Although this is of no importance in the final result (the amplitude of the frequency component is zero), it can complicate the interpretation of the phase spectrum.

As already noted, the calculation of the discrete FT can be carried out using Equation (40), but for most real applications involving a substantial number of data points, the application of this equation is impractical due to the large number of operations required (on the order of \(N^2\)). For this reason, few applications employed the FT until the mid-1960s, when the FFT algorithm was popularized by Cooley and Tukey.\(^{2}\) The FFT greatly reduced the number of operations required (of the order of \(N \log N\)) and made transformations practical for a wide variety of problems. Although beautifully elegant in its partitioning of the problem, a somewhat annoying requirement of the original algorithm was that it required the number of points to be equal to a power of two. Improvements on the original algorithm have largely removed this restriction (although they are not quite as efficient), and FTs are now calculated with ease for most signals of moderate length using a variety of software packages.

One of the principal applications of the FT is the conversion of data recorded by instruments such as FTIR spectrometers, where it is needed to transform the measurements from the time domain to the frequency domain (or vice versa) before it can be interpreted in the conventional way. In addition to this, the FT is used for a great many signal manipulation purposes, such as smoothing, deconvolution, and interpolation. Some of these applications are now illustrated.

A great deal of the utility of the FT in signal processing derives from the convolution theorem, which states that the convolution of two signals in the time domain is equivalent to the element-by-element multiplication of the functions in the frequency domain. Mathematically, if \(g\) and \(h\) are functions in the time domain and \(G\) and \(H\) are the corresponding functions in the frequency domain, Equation (47) holds:

\[ g(t) * h(t) = \text{IFT}[G(f)H(f)] \]  

(47)

where the asterisk indicates the convolution of the two functions and IFT indicates the inverse transform. As digital filtering is the convolution of filter coefficients with a noisy signal, this immediately leads to an application in Fourier smoothing. The difference here is that we can specify the transfer function of the filter exactly through its FT. This is illustrated in Figure 26 with the smoothing of a noisy Gaussian. The FT of the noisy signal is first calculated and then both the real and imaginary parts are multiplied by the ideal transfer function which sets all of the high frequencies where there is no significant signal.

![Figure 26 Fourier filtering of a noisy signal.](image)
contribution to zero. Note that both positive and negative frequencies must be included in this multiplication, which is why the transfer function looks somewhat different than that shown earlier. After the multiplication is carried out, an IFT is applied to the result to give the smoothed signal in the time domain.

Although this procedure works very well, it has some drawbacks. First, it is slower than a digital filter and cannot be done in real time because the entire signal is required. Second, artifacts such as the oscillations near the tails of the peak are often observed due to the sharp transition of the transfer function. More severe distortion can result if the cut-off frequency is moved closer to the signal components, but there will be less noise reduction if it is moved to higher frequencies. To avoid this characteristic of the ideal filter, a more gradual decrease in the transfer function is often employed. Such a function is sometimes referred to as an apodization function. If the FT of the pure signal is designated as $S(f)$ and that of the noise as $N(f)$, it can be shown that the transfer function of the optimal, or Weiner, filter is given by Equation (48):

$$\Phi(f) = \frac{|S(f)|^2}{|S(f)|^2 + |N(f)|^2}$$  \hspace{1cm} (48)

This is the transfer function that will give the optimal reproduction of the true signal in the least-squares sense. The difficulty with applying this filter is in the estimation of $S(f)$ and $N(f)$ for the pure signal and noise, but that is beyond the scope of this article.

In addition to convolution, the FT can aid in the deconvolution of two signals. If $h$ represents the convolution of two signals, $f$ and $g$ in the time domain ($h = f * g$), where $g$ is known, the deconvoluted signal $f$ can be obtained through an element-by-element division in the frequency domain (Equation 49):

$$f(t) = \text{IFT} \left\{ \frac{H(f)}{G(f)} \right\}$$  \hspace{1cm} (49)

This is illustrated in Figure 27 where a simulated spectral doublet has been convoluted with the slit function of the spectrometer which smears the two peaks. Through Fourier deconvolution, it is seen that the original line shape can be recovered. Practically speaking, there are a number of difficulties associated with this procedure. First, one of the convolution functions needs to be known in advance. Second, the division presents problems when the denominator in Equation (49) is close to zero and adjustments need to be made in this case. Depending on how this is done, artifacts such as those apparent in the baseline of the deconvoluted spectrum of Figure 27 can result. Finally, the presence of noise can lead to additional complications in the deconvolution. In a best-case scenario, however, this type of deconvolution can be used to improve the resolution of the instrument after the measurements have been obtained.

As a final example of the use of the FT in signal processing, Figure 28 shows an example of function interpolation. This procedure, which has been referred to as the zoom FT, is based on the fact that the Nyquist frequency is directly related to the sampling frequency. If the FT of a signal is padded with zeros at the frequency limit where there is little signal contribution, the Nyquist frequency can be increased,
and consequently the sampling interval decreased. This essentially interpolates the function between existing measurements. Although this approach has been used in certain applications, such as locating the peak maxima in undersampled mass spectrometry peaks, it should be used with caution because the zero-padding makes implicit assumptions about the form of the function between the original points which may be erroneous.

6.3 Wavelet Transforms

Although a more recent development than the FT, the WT approach is gaining increased acceptance as a signal processing tool for the analytical chemist. The first applications in the chemical literature of the WT as a denoising, smoothing and data compression procedure appeared in the early 1990s, and their frequency of mention has increased steadily. The utility of the WT for noise reduction purposes rests largely on its decomposition of the signal into successive levels of high- and low-frequency components. In data compression applications the decimation filter property of the WT is useful, effectively reducing the number of elements needed to represent the signal with minimal loss of information. Numerous algorithms for the WT have been devised, with the most popular being the recursive form of the discrete wavelet transform (DWT) attributable to Mallat,\(^{35}\) the generalization of which is known as the wavelet packet transform (WPT).\(^{30,36}\) An increasing number of software packages are now available for performing DWTs and WPTs as well as related functions in a relatively straightforward manner.

Like the FT, the WT converts the data into a more useful domain for signal processing by projecting the observed signal onto a set of orthogonal basis functions. In the FT, the signal is projected into the frequency domain using sinusoids as the basis functions. In the frequency domain, the basis functions are localized, but when transformed to the time domain the functions extend globally along the time axis. In contrast, the WT uses basis functions that are both localized in the frequency and time domains to project the data into the wavelet domain. The WT, therefore, has perhaps a more intuitive appeal for some who routinely deal with signals that are time localized, such as chromatographic or spectroscopic measurements. A very readable introduction to denoising, smoothing and data compression procedure of approximation. In order to determine the appropriate basis vectors for reconstruction of the signal, it is useful to examine the coefficients of the approximation and detail levels. This is analogous to examining the coefficients of a Fourier decomposition, except that the wavelet decomposition is arranged in two dimensions – time and frequency. As in Fourier denoising applications, it is desirable to eliminate or reduce coefficients believed to be associated with noise, and retain coefficients reflecting information in the original signal. In the WPT, however, not only must coefficients be selected in the frequency realm, but also in the level of approximation. In order to determine the appropriate basis vectors for reconstruction of the signal, it is useful to examine the approximation and detail vectors resulting from the transform. A simple example of denoising using the WPT is presented in Figure 32. In this example, the WPT has only been carried out to two levels for purposes of illustration. At level 2, it is apparent that three of the
Figure 29 Illustration of (a) the DWT and (b) the WPT.

Figure 30 Illustration of the $L$ and $H$ matrices (four coefficients) used in the WPT to generate the approximation ($a$) and detail ($d$) vectors, respectively, at successive levels of resolution. For the Daubechies-4 wavelet, the coefficients are $c_1 = 0.4830$, $c_2 = 0.8365$, $c_3 = 0.2241$, and $c_4 = -0.1294$. Note that the coefficients will not change for different levels of resolution, but the size of the filter matrix will depend on $n$, the number of channels in the signal at the previous level of resolution.

four vectors contain little useful information, so these are set to zero before the inverse wavelet transform (IWT) is carried out, resulting in a reduction in the noise. It should be noted that no attempt was made to optimize the denoising in this example, and decompositions to additional levels may have allowed further improvement. Denoising with the WT involves more options than that for the FT, such as the selection of a set of basis functions, the level of decomposition used, and the choice of basis vectors to set to zero.

Because of the wide range of possibilities, algorithmic methods of basis selection have been proposed, with the most intuitive and successful using the minimum entropy (or maximum information) condition of Coifman and Wickerhauser. Another method of selecting the best basis vectors is the minimum description length (MDL) method. The MDL is primarily used when data compression is desired, and proceeds on a version of the principle of parsimony, seeking the basis vectors which contain the most information in the fewest coefficients.

With the best set of basis vectors selected from the full decomposition, additional signal adjustment can be made by using hard or soft thresholding measures on the remaining coefficients. In hard thresholding, coefficients above a preset threshold are retained, whereas coefficients below this level are discarded. Soft thresholding can also entail zeroing of coefficients below the threshold,
but coefficients above the threshold are also typically shrunk towards zero by an amount inversely proportional to their magnitude. Evidently the selection of the threshold value is crucial in these procedures, and several methods exist for estimating the optimal threshold value, including estimating the threshold based on the level of noise, and setting the threshold as a percentage of the largest coefficient. Typical hard, and soft thresholding functions are shown in Equations (50) and (51):

**hard thresholding:**

\[ c_{\text{new}} = \begin{cases} 0, & \text{if } |c_{\text{old}}| < T \\ c_{\text{old}}, & \text{if } |c_{\text{old}}| \geq T \end{cases} \]  

\( \text{(50)} \)

**soft thresholding:**

\[ c_{\text{new}} = \begin{cases} 0, & \text{if } |c_{\text{old}}| \leq T \\ \text{sign}(c_{\text{old}})(|c_{\text{old}}| - T), & \text{if } |c_{\text{old}}| > T \end{cases} \]  

\( \text{(51)} \)

As an alternative to using threshold values to select relevant coefficients, wavelet smoothing can be achieved by simply discarding detail vectors and performing the inverse WPT from the desired approximation vectors. Although this technique has the potential to achieve greater compression ratios, it is a perilous operation when one lacks knowledge of the location of relevant information in the wavelet decomposition – some useful information may well be contained in some detail vectors. With this possibility looming, it is generally recommended that wavelet smoothing by discarding detail vectors be reserved for situations in which extensive knowledge of the signal allows for educated detail removal.

With basis selection, and coefficient adjustment complete, it is possible to approximate the original signal in the original resolution. This domain is revisited by passing the selected basis vectors back through the high- and low-pass filters. To make the filters interpolation rather than decimation filters, the conjugates of \( H \), and \( L \) are employed. Based on the orthonormality of the
two matrices, the conjugates of $H$ and $L$ are equivalent to the transposes. Therefore the IWT proceeds straightforwardly through the up-sampling filters $H^T$ and $L^T$ (transposes of the matrices in Figure 31) until the desired resolution is achieved, with the denoised signal resulting.

Figure 33 illustrates the utility of the WT in signal denoising using a simulated spectrum. White noise was added at a level corresponding to $\sigma_{\text{noise}} = 0.1$, giving the noisy spectrum in Figure 33(a). The first wavelet chosen for the transform was the Daubechies-4 ($c_1 = 0.4829$, $c_2 = 0.8365$, $c_3 = 0.2241$, $c_4 = -0.1294$). Best-basis selection was performed using the minimum entropy procedure of Coifman, and hard thresholding was used on the chosen basis vectors. The results of the overall wavelet denoising with the Daubechies-4 wavelet are shown in Figure 33(b).

To illustrate the effect that different wavelet families can have, the Coiflet-3 wavelet was also used, and the results shown in Figure 33(c). In practice, a comparison would more probably be made between different members of a family to find the best result.

### 6.4 Hadamard Transforms

Like other transform methods, the HT can be thought of as a transformation from one space to another, with a Hadamard matrix acting as the transformation matrix.\(^{44-47}\) HTs are one method of gaining the Felgett advantage, or multiplex advantage, as it is often called.

The multiplex advantage is a statistical gain in SNR as a result of simultaneously measuring multiple spectral resolution elements. In contrast to dispersive methods, in which a single spectral element is measured at a time, multiplex methods measure several coincident spectral elements simultaneously. In order for the multiplex design to prove beneficial from an SNR perspective, the noise in the signal must be considered to be independent of the strength of the incident radiation (i.e., detector noise is the overwhelming noise source). If this condition is met, simple propagation of error reveals that the SNR of a multiplex instrument, relative to a dispersive instrument is $\sqrt{N}$, where $N$ is the number of spectral elements that impinge on the detector at any one time.

Although FT spectrometers are perhaps the best known instruments to utilize the multiplex advantage, the HT spectrometer is also a valuable option. The principles of the HT are based on the concept of Hadamard matrices. As noted above, the benefit of the HT stems from propagation of measurement error into the estimated spectral values. If one observation is made with an inherent detector error of $e$, then the error in the estimated value is $e$. However when we wish to estimate several unknowns we can reduce the error associated with a particular estimate by measuring groups of unknowns together in a well-designed fashion. We can subsequently use systems of linear equations to solve for the estimates, and decrease the error in those estimates in the process.

The classic analogy is to a weighing scheme for several unknown objects. In the example sketched here, four objects are weighed in experiment A one at a time, with a detector noise level of 0.1. (Experiment A is analogous to a dispersive spectrometer.) Experiment B, two or three objects are weighed together at any one time, although we still only have four total measurements to estimate each individual object’s mass. (Experiment B is analogous to a single detector HT spectrometer.)

#### Experiment A

\[
\begin{align*}
W_A m &= x + e \\
W_A^{-1} m &= x + W_A^{-1} e
\end{align*}
\]

#### Experiment B

\[
\begin{align*}
W_B m &= x + e \\
W_B^{-1} m &= x + W_B^{-1} e
\end{align*}
\]
Here the \( x_i \) terms represent the observed reading on the scales, and the \( m_i \) terms represent the estimated mass of the \( i \)th object. Through propagation of error, it is relatively easy to show that if the measurement uncertainties for the \( x_i \) terms are independent and given by \( \sigma_x \), then the uncertainties in the masses will be given by Equation (52),

\[
\sigma_{m_i}^2 = \sigma_x^2 \operatorname{diag}[(WW^T)^{-1}]
\]  

(52)

where ‘diag’ indicates extraction of the diagonal elements. Solution of this equation using \( \sigma_x = 0.1 \) gives \( \sigma_m = 0.1 \) for all masses in experiment A, whereas the values for experiment B are 0.067, 0.088, 0.088, 0.088 for \( m_1 - m_4 \), respectively. Clearly, noise reduction in the estimates has occurred via the multiplex advantage.

In HT spectrometers, the weighing design matrix as shown above is embodied by a mask (Hadamard mask) that physically impedes the incidence of some spectral elements while letting others pass through to the detector. Whereas early HT instruments used a moving mask, the current inclination is toward stationary masks whose codes are changed using electrooptical devices. In true HT spectrometers, light is not only blocked from the coagulating detector, but it is also reflected back to a subtracting detector, such that the measured total intensity is the difference of the adding and subtracting detectors. The weighing matrix in these scenarios, \( \mathbf{H} \), is a series of 1 and \((-1)\) values representing which elements are subtracted and which are added. These matrices are designed based on Hadamard mathematics. When this arrangement is used, the SNR enhancements observed in FT instruments can be achieved. In practice the HT instruments are difficult to construct to the required specifications and thus single-detector instruments are principally used. The weighing matrix used in these systems is the \( \mathbf{S} \) matrix, and the elements are similar to the weighing matrices shown above (zeros and ones). \( \mathbf{S} \) matrices can be easily constructed from Hadamard matrices by removing the first row and column of \( \mathbf{H} \) and changing all \(-1\) elements in \( \mathbf{H} \) to zeros in the \( \mathbf{S} \) matrix. Although closely related to the Hadamard matrices, \( \mathbf{S} \)-matrix methods do not afford the same enhancement in the SNR as \( \mathbf{H} \)-matrix methods because, with \( N \) spectral elements, only \((N+1)/2\) may be measured at any one time.

Like the interferogram resulting from the Michelson interferometer, the encodegram is the resulting signal output from a Hadamard mask experiment. The encodegram relates the radiative flux reaching the detector with the position of the Hadamard mask. To convert this signal in the Hadamard domain to the desired frequency domain the inverse HT is used. Given the properties of \( \mathbf{S} \) (orthonormal rows/columns and square) this is easily accomplished by convolution of the encodegram with the inverse of \( \mathbf{S} \), i.e. \( \mathbf{S}^{-1} = \mathbf{S}^T \).

With the use of electrooptic Hadamard masks come new problems with the standard HT. Although these stationary masks remove the problem associated with the continuously moving parts of the FT instruments, nonidealities in the opacity or transmissiveness of the mask require adjustments to the weighing matrices.\(^{47}\)

When noise is independent of the signal intensity, as is the case when detector noise dominates, Hadamard multiplexing can prove a useful method of improving the SNR of the spectral estimates. In true Hadamard multiplexing noise reduction follows the general formula of Equation (53):

\[
\sigma_{HT} = \frac{\sigma}{\sqrt{N}}
\]

(53)

where \( \sigma_{HT} \) is the standard deviation of the estimated elements using HT methods, \( \sigma \) is the standard deviation of the detector output (equivalent to the noise level in the same experiment using a monochromator), and \( N \) is the number of spectral elements to be estimated. However, most HT instruments employ \( \mathbf{S} \) matrix methods which, at best, allow reduction of the uncertainty of the estimate according to Equation (54):

\[
\sigma_{HT} = 2\frac{\sqrt{N}}{N+1}\sigma \approx 2\sigma \sqrt{\frac{2}{N}}
\]

(54)

Although the HT has found some utility in analytical applications and is likely to continue to do so in situations for which multiple channel detection or FT methods are unfeasible, its implementation has not been extensive. With the increasing prominence and quality of multichannel detection systems, the multiplex approach of the HT to signal processing is likely to have limited future utility.

7 HIGHER-ORDER SIGNAL PROCESSING

The bulk of this article centers on signal processing methods for first-order data sets – those cases where the signal can be represented as a vector of measurements. In recent years, however, there has been an increased emphasis on the use of higher order data in analytical chemistry. This is particularly true for second-order data sets (matrices of measurements), but increased use of third-order data is also apparent in the literature. This phenomenon can be attributed to three main factors: (a) the demand for new kinds of analytical information and more efficient analytical methods; (b) the increased availability of multichannel detectors, such as photodiode arrays and charge-coupled
devices, as well as rapid scanning instruments; and (c) the development of chemometric methods capable of dealing with multidimensional data. Techniques such as multivariate calibration and pattern recognition are now used routinely, and their application has led to the increased need for signal processing for higher-order data.

In discussing signal processing for higher-order data, it is necessary to make the distinction between the order of the data and the order of the signal. A defining characteristic of a signal is that it exhibits correlation in the ordinal variable for some domain, so a higher-order signal should exhibit correlation in the ordinal variable for each dimension. For example, a collection of spectra from different samples for a multivariate calibration or pattern recognition study would not normally exhibit correlations among the samples, and so this second-order data set can be regarded as a collection of first-order signals. In contrast, spectra obtained during a chromatography or kinetics experiment would result in second-order signals in a second-order data set, because there would be a relationship among the spectra in the time domain. Other combinations are also possible. For instance, if fluorescence emission–excitation spectra were collected for an arbitrary series of samples, we would have second-order signals composing a third-order data set.

For data sets that are composed of first-order signals, signal processing is generally restricted to first-order methods such as those already described. Nevertheless, such signal processing can still have effects across multiple orders and for that reason may be regarded as even more important for higher-order data than for the first-order case. For example, the presence of a variable baseline offset or drift between sample spectra can be detrimental to multivariate calibration methods, but this effect can be minimized by derivative filtering in the spectral domain. The application of such techniques prior to data analysis falls under the subject area of data preprocessing, and includes such methods as mean-centering, baseline subtraction, scaling, smoothing, differentiation, and domain transformation. Choice of an appropriate preprocessing method can be critical and often determines the success or failure of a multivariate analysis application. A complete discussion of these methods is beyond the scope of this article; however, many appropriate texts on chemometrics give more information.\(^{13,48–50}\)

![Figure 34](image) Illustration of the calculation of filter coefficients for a 3 × 3 quadratic filter with an interaction term.
For signals that are truly higher order, first-order signal processing methods can still be used, but other options are also available. In large part, these are extensions of the first-order methods which have already been discussed. In the case of second-order signals, for example, there are two-dimensional (2D) smoothing methods, 2D FTs and 2D WTs. The application of these techniques can offer greater power and flexibility since the characteristics of the signals in both dimensions can be exploited. For example, in the case of spectra collected during a chromatography experiment (a spectrochromatogram), filtering using a nine-point moving average filter in either the time or spectral dimension requires convoluting each signal vector with a $1 \times 9$ smoothing vector. However, 2D smoothing could use a convolution of the full matrix with a $3 \times 3$ smoothing matrix and the same level of noise reduction would be achieved (in the case of a moving average filter) with less distortion. Understandably, the use of 2D techniques introduces greater complexities in terms of computation, implementation, interpretation and optimization than their one-dimensional (1D) counterparts, but these can be overcome.

As most higher-order signal processing methods are extensions of their 1D counterparts, a detailed discussion is not presented here. However, one example of 2D smoothing is presented as an illustration. In this example, a $3 \times 3$ polynomial smoothing filter is used. To demonstrate the design, a quadratic filter with an interaction term was chosen, with the corresponding Equation (55):

$$
\hat{y} = b_0 + b_1 x_1 + b_2 x_2 + b_3 x_1^2 + b_4 x_2^2 + b_5 x_1 x_2
$$

(55)

where $x_1$ and $x_2$ represent the two ordinal variables. The generation of filter coefficients requires the unfolding of matrices representing the ordinal variables and the process is illustrated in Figure 34. The resulting smoothing coefficients are (Equation 56)

$$
C = \begin{bmatrix}
-0.111 & 0.222 & -0.111 \\
0.222 & 0.556 & 0.222 \\
-0.111 & 0.222 & -0.111
\end{bmatrix}
$$

(56)

The result of the application of this filter to the noisy fluorochromatogram of a mixture of pyrenes in Figure 35(a) is shown in Figure 35(b). Although some noise reduction results, it is not as great as that obtained with a simple $3 \times 3$ moving average filter, as shown in Figure 35(c). It is clear that the 2D filter involves the same trade-off between noise reduction and distortion as the 1D filters, but the optimization in the 2D case involves a greater number of options, such as the size and order in each dimension and the inclusion of interaction terms. So far, unlike first-order methods, there have not been extensive studies on the relationship between second-order signal processing methods and the signals they are applied to in chemistry, but this is likely to change as higher-order data become more prevalent.

8 CONCLUSIONS

This article provides a general description of some of the signal processing tools commonly employed in analytical chemistry. As a general principle, it is apparent that all signal processing methods make assumptions about the models for signals and for noise in order to distinguish the two. The power of a particular method in a given application depends on the nature of the assumptions made (very general or very restrictive) and the extent to which they are valid. It is also true that the use of signal processing methods is a double-edged sword. Although the quality of information may be enhanced, it is also possible to distort the signal to the point where results become unreliable. Clearly, a knowledge of the nature of signals, noise and
the capabilities of signal processing methods is essential. For this reason, a significant portion of this article is dedicated to the practical aspects of implementing different methods and their effects on signals. Developments in signal processing applications to analytical measurements will no doubt continue, particularly for digital signals. Although some methods, such as polynomial smoothing and FT-related techniques, will continue to permeate all areas of analytical chemistry, other methods, such as Kalman filtering and HTs, have found more specialized niches. The impact of WTs is evidence of the ongoing research in signal processing applications. Undoubtedly, future developments will exploit greater computational abilities and present new challenges in application and interpretation. As noted in the previous section, applications to higher-order methods will be a focus of research. In any case, it is apparent that, whether it is the enhancement of fuzzy images from atomic microscopes or the removal of background signals in remote sensing from space, signal processing methods will continue to play a key role in all aspects of analytical chemistry.

REFERENCES

In this contribution different methods for soft modeling data analysis are reviewed. Soft modeling approaches attempt the description of a system without the need of an a priori model postulation, physical and/or chemical. The goal of these methods is the explanation of data variance using the minimal or softer assumptions about data. Most of these soft modeling approaches are based on factor analysis (FA) decompositions of experimental data matrices. These decompositions are done by pure mathematical means and allow the identification of the number of data variance sources, their qualitative and, eventually, quantitative estimation. Results of soft modeling data analysis are useful to validate hard modeling results and also for investigation of complex chemical systems. In this contribution, soft modeling data analysis methods described can be applied to one data matrix or to several data matrices (three-way data sets). The purpose of these methods are mainly exploratory analysis and resolution of mixture data sets. Within the latter group, special attention is devoted to multivariate curve resolution (MCR) techniques and their extension to three-way data analysis. Three examples of application are given covering the chromatographic coelution of mixtures of pesticides using liquid chromatography/diode-array detection (LC/DAD), the infrared (IR) spectral data analysis from multiple runs of an industrial process and the interpretation of thermodynamic and conformational transitions of polynucleotides using spectrometric titrations.

1 INTRODUCTION

Data modeling and data fitting in chemical sciences has been traditionally done by hard modeling techniques, i.e. data are tested against a model based on physical and chemical laws and the parameters of this model are obtained by least-squares curve fitting optimization techniques. This approach is valid for well-known phenomena and laboratory data, where the variables of the model are under control during the experiments and only the phenomena under study affect the data. However, this ideal situation is not obeyed in many circumstances in chemistry, specially in analytical chemistry, when natural samples or unknown processes are investigated. Complex phenomena like those involving macromolecular compounds or industrial processes, where physical parameters cannot be appropriately fixed, are typical examples not solved by the traditional model-based data treatments. Alternative approaches to hard modeling have been proposed. In particular, soft modeling approaches attempt the description of a system without the need of an a priori model postulation, physical and/or chemical. The goal of these methods is the explanation of data variance using the minimal or softer assumptions about data. Most of these soft modeling approaches are based on FA decompositions of experimental data. These decompositions are done by pure mathematical means and allow the identification of the number of data variance sources and often their qualitative and, eventually, quantitative estimation. Results of soft modeling data analysis are useful to validate hard modeling results and also for investigation of complex chemical systems. In this contribution, soft modeling data analysis based on FA techniques and, especially, MCR techniques are reviewed and some examples of application are given at the end of the chapter.
sample involves usually the measurement of several independent parameters (e.g. concentrations of constituents, pH, temperature, etc.) or the recording of a multivariate instrumental response (e.g. a spectrum). Modern instrumentation able to acquire and store data easily and powerful computers that can handle efficiently large amounts of information have promoted the transition from the univariate to the multivariate domain. However, enormous amounts of raw experimental measurements reveal little about a chemical problem unless they are treated with the appropriate data analysis method.

In this and subsequent sections, the explanations are focused on data sets that can be organized in a table or, in mathematical words, in a data matrix. These data matrices can be the result of organizing in rows the multivariate response of a series of samples or the responses recorded at different stages of a chemical reaction (see Figure 1). The general terminology adopted calls objects the parameters that define the rows and variables the parameters that define the columns in a data matrix.

Figure 1 Examples of multivariate data sets. (a) Matrix of samples analyzed voltammetrically. \(i_j\) is an intensity measurement collected for the \(i\)th sample at the \(j\)th potential. (b) Spectrometric monitoring of a kinetic process. \(A_{ij}\) is an absorbance reading recorded at the \(i\)th reaction time for the \(j\)th wavelength.

FA started as a method to find out the underlying structure in these data matrices, i.e. to know how many sources of variation (factors) are needed to describe the data sets and, if possible, to identify the chemical nature of these factors. The first step in this process is called abstract FA or principal component analysis (PCA) and establishes a bilinear model of variation in the data set by using abstract variables. The second and more important step links these abstract factors with chemical sources of variation and can be done using several procedures that will be described below.

The first problem associated with large data sets is “how to look at them”. The observation of hundreds or even thousands of numerical values does not provide any straightforward information, but displaying the raw data in plots does not seem possible due to the size of the data space (e.g. displaying samples whose spectra have 100 absorbance readings would imply drawing a plot with 100 axes, when the human eye can cope with, at most, three-dimensional figures). Trying to find out methods to visualize multidimensional data spaces, the next question is if all the variables are necessary to describe properly the variation in our data set. There are often many original variables that are clearly correlated and, as a consequence, most of the information that they provide is redundant. In view of this fact, a plot of the data set could be drawn either using the most representative and uncorrelated original variables or replacing the pool of original variables by a reduced set of efficient abstract variables, calculated as a linear combination of the original ones. These new variables, which are completely uncorrelated and describe the main directions of variation of the data set, are the so-called principal components.

Figure 2 shows graphically how principal components are designed with a simple example. The data set used consists of a series of spectra for solutions of a pure substance with different concentrations recorded at three different wavelengths. All the points plotted lie in a straight line because spectra of the same pure substance differ only in intensity and not in shape. It can be seen that the information contained in the plot of the spectra in the original space could be kept using only one axis drawn in the direction of maximum variation of the data set. This axis is the first principal component (PC1) and allows the reduction of the dimensions of the data space from three to one (note that if the spectra for the pure substance had been recorded at \(m\) wavelengths, the reduction in dimensions would have gone from \(m\) to one). In general, for complex systems, more than one principal component is needed, but the reduction of dimensions from the original space of variables to the space of principal components is always drastic.
The principal components are axes (vectors) which are orthogonal to each other, i.e. completely uncorrelated (eigenvectors). Each new principal component is calculated so as to describe the largest direction of variation in the data set that has not yet been described by other principal components. This means that they decrease gradually in importance because every time the remaining variation in the data set is less. Given a data set with \( m \) rows and \( n \) columns \((m \times n)\), the number of principal components that can be calculated is \( m \) or \( n \), whichever is the smallest; however, only a few of them are needed to obtain a good picture of the variation in the original matrix. Thus, for any data matrix, the principal components can be divided into two groups: those which account for the chemical variations in the data set, which are calculated first and are usually few; and those which are related to the noise description. Only the first group will be used to model the data matrix.

The concepts that relate the objects and the variables of the original data matrix to the space of principal components are the scores and the loadings, respectively. The scores are the coordinates of each object in the principal component axes. The loadings express how large the contribution of each original variable is to the principal components. As mentioned above, principal components are obtained as weighted sums of the original variables. These weights are the loadings and their magnitude (in absolute value) is proportional to the importance they have in the description of the principal component. A variable with large loadings for a certain principal component is significantly correlated to this abstract variable, i.e. their directions in the data space are similar.

Figure 3 shows the PCA results of a real example related to an environmental problem. The data set in this case is formed by 22 sediment samples collected in the northwestern Mediterranean Sea (objects) for which the concentration of 96 compounds of anthropogenic and biogenic origin (variables) has been determined. The first two principal components explain around 70% of the total variation in the data set. Samples close to each other in the score plot of PC2 versus PC1 are similar. The PCA allowed the identification of several groups of samples related, in this case, to diverse sampling areas with clearly different compound apportionment. The loading plot linked principally the concentrations of compounds coming from land-based pollution sources to the first principal component, whereas those due to atmospheric deposition were mainly related to the second principal component. Correlated variables were close to each other or placed along the same straight line through the origin in the loading plot. The information in the scores plot and the loadings plot can be put together in a biplot, which relates the objects and variables of a data set. A biplot helps to characterize the different clusters of objects found in the data set. Thus, in this example, the cluster of samples collected in the Ebro prodelta (region 3 in Figure 3), which extends primarily along the PC1, is mostly related to the variables associated with this first principal component, namely those compounds coming from land-based pollution sources. The other two groups of samples, collected in the open sea, have an expected larger contribution of compounds coming from the deposition of airborne particles.

Mathematically, the relationship between the original data space and the principal component space is expressed by Equation (1):

\[
D = TP^T
\]  

(1)

where \( D \) \((m \times n)\) is the original data matrix, \( T \) \((m \times npc)\) is the matrix of scores and \( P^T \) \((npc \times n)\) is the loading matrix. \( npc \) is the number of principal components related to chemical sources of variation in the data set. All columns in the \( T \) matrix are orthogonal to each other and so are all rows in \( P^T \). This is the data decomposition obtained using the nonlinear iterative partial least squares (NIPALS) algorithm, by far the most used when FA was introduced in chemistry (it is important to note that the rows of the \( P^T \) matrix are the eigenvectors obtained from the diagonalization of the covariance matrix \( Z = DD^T \)). Nowadays, the most popular algorithm is singular value decomposition (SVD), which provides a matrix decomposition closely related to Equation (1), though formally
Figure 3 Scores plot, loadings plot and biplot of an environmental data set. Each row in the original data matrix refers to a sampling site (CR) and each column to the concentration of an organic compound (C). Figures in the scores plot indicate different geographical zones (1 and 2 are open sea zones, whereas 3 is a river delta). Letters in the loadings plot indicate the origin of the contaminants (A refers mainly to deposited atmospheric pollutants and B mainly to anthropogenic or biogenic pollutants).

different. Equation (2) is provided by SVD:

\[
D = USV^T
\]

where the columns in \( U \) and the rows in \( V^T \) are orthonormal vectors, i.e. unit length orthogonal vectors. The information contained in \( U \) and in \( V^T \) is related to the scores matrix \( T \) and the loading matrix \( P^T \) respectively. \( S \) is a diagonal matrix, whose diagonal elements are the singular values of \( D \), i.e. the square root of the eigenvalues. The mathematical expressions that are generally used to link the NIPALS and SVD results are given in Equations (3) and (4):

\[
T = US \tag{3}
\]

\[
V = P \tag{4}
\]

though some other combinations have also been reported.\(^6\)

The singular values are ranked in descending order of magnitude along the diagonal of the \( S \) matrix and their numerical values are related to the importance of their associated principal component. When the singular values (or the logarithm of the eigenvalues) of a matrix are plotted vs the principal component number, there is often a clear cut-off point between the eigenvalues connected with chemically meaningful factors and those describing noise contributions. This kind of plot is frequently used to find out how many principal components (factors) are needed to describe the sources of variation in a data set.

Deduction of this number of principal components is sometimes not an easy task because of the presence...
of nonrandom experimental noise. Besides this visual method, several methods have been proposed:\(^{(1)}\) methods based on the previous knowledge of experimental error; and approximate methods which do not require previous knowledge of experimental noise. Obviously, the first type of method is preferred when the experimental error is known. However, this knowledge is not available in many circumstances and the methods of the second group should be used. One of the methods which has been found to be useful and does not require previous knowledge of the experimental error is the indicator function (IND) proposed by Malinowski.\(^{(7)}\) This function reaches a minimum when the correct number of components has been chosen. It is more sensitive than other functions proposed for the same purpose. There are also other statistically sounder methods, like cross-validation\(^{(8)}\) methods. These methods consist of the elimination of a reduced data subset of the whole data set, for instance one row (or several rows) of the data matrix, and the determination of the eigenvalues and eigenvectors of the reduced data matrix which does not have the eliminated rows. All these eliminated rows are then estimated using different numbers of components and the differences between the reproduced values and those which were eliminated are calculated and expressed in a table. The process is repeated for all the rows of the matrix and the prediction errors are summed, giving the function PRESS (prediction error sum of squares). Once this function has been calculated, different approaches can be applied; the simplest one is just plotting it for different numbers of components and looking for a minimum or for a nonstatistical difference between two consecutive numbers of components. Malinowski\(^{(9)}\) has also proposed other methods based on the concept of reduced eigenvalue, which theoretically should follow a normal distribution. The significant reduced eigenvalues will be statistically larger than the average variance associated with the error eigenvalues, and therefore, distinguishable from them. Malinowski\(^{(11)}\) gives more details about these methods.

The value of PCA for exploratory data analysis has been shown in this section and in many examples published along the history of chemometrics; however, the abstract model provided by PCA is useful for other purposes. Figure 4 shows the bilinear PCA model in detail.

According to Figure 4, the PCA decomposition of a matrix can be written as in Equation (1) or as the sum of bilinear terms as shown in Equation (5):

\[
D = t_1p_1^T + t_2p_2^T + \cdots + t_np_n^T
\] (5)

In using PCA as the starting point to find the underlying model of a chemical data set, the most important requirement is that this set should be intrinsically bilinear, i.e. should have the model form of Equation (5). Happily, many chemical models follow this pattern. A known example is a spectrometric data set, which behaves according to the Beer–Lambert law as shown in Equation (6):

\[
D = \epsilon_1c_1 + \epsilon_2c_2 + \cdots + \epsilon_ic_i
\] (6)

where \(D\) is a matrix of composite spectra, \(c_i\) is the vector that contains the concentrations of the \(i\)th component in the different samples and \(\epsilon_i\) is the vector of absorptivities for the \(i\)th component. As can be seen, Equations (5) and (6) are formally identical. Such a similarity suggests that PCA can be useful to decide which size the simplest bilinear model to describe a data set should have, but once this information is obtained, the chemist may be more interested in a model equally sized where the scores and loadings be replaced by terms with a chemical meaning.

At the beginning of this section, it was pointed out that principal components are orthogonal axes that describe the directions of largest variation in a data set. These directions, however, are not necessarily the most informative. In these cases, the best option is performing a rotation of the original axes so that the new axes span the same data space, this being more easily interpretable. For example, for a system with two principal components, these components can be replaced by any other couple of axes which lie on the same plane defined by the two principal components. Some rotation procedures are based on mathematical criteria,\(^{(10)}\) such as the VARIMAX rotation, which replaces the principal components by the set of orthogonal axes of maximal simplicity.\(^{(11)}\) When two axes are compared, e.g. [0.3 0.3 0.3] and [0 0 1], the simplest one, [0 0 1], has its nonnull loadings grouped over a smaller number of variables. In chemistry, these simple factors...
are often closer to the real ones and, when not, they help to simplify the interpretation of the data set.

Despite the benefits provided by VARIMAX and other abstract rotations, the rotated axes can seldom be identified as chemical factors. Whenever this is possible, the use of rotation procedures which take into account chemical information is preferred. This is the basis of target factor analysis (TFA), which replaces the principal component axes by real factors with chemical meaning.\(^1\) This is done after testing individually a pool of potential real factors (targets) which may be useful to build a chemical model for the data set.

TFA works by following the steps below:

1. determination of the number of factors of the data set (PCA);
2. selection of potential real factors (targets);
3. target testing;
4. data reconstruction with the targets accepted.

A crucial step in this method is the selection of the targets. The appropriate choice of these vectors and, consequently, the quality of the final model obtained, would largely depend on the chemical knowledge of the data set. The criterion to choose a target can be theoretical or empirical, or simply rely on previous experience but, in all cases, the target selected should potentially justify part of the variation in the data set. There is no limitation on the number of targets to be tested.

Figure 5 shows two real examples of data sets with their associated targets. The example proposed in (a) is a matrix whose columns are mixture spectra. The targets, which are proposed to replace the score vectors, would be pure spectra of compounds that may be present in the mixtures. TFA would link the models in Equations (5) and (6).\(^2\) The example in (b) belongs to the field of linear solvation energy relationships (LSER).\(^3\) LSER are linear models that explain solvent-dependent variations in solute properties as a function of changes in certain solvent properties (see Equation 7).

\[
XYZ = (XYZ)_0 + s_1 a_1 + s_2 a_2 + \cdots + s_i a_i \tag{7}
\]

\(XYZ\) is the solvent-dependent solute property, \((XYZ)_0\) is the value of the \(XYZ\) property in a hypothetical solvent with null interaction with the solute, \(s_i\) is a solvent property responsible for the variation of the solute property and \(a_i\) is the weight coefficient related to the contribution of \(s_i\) in the variation of the solute property \(XYZ\). Each column in the data matrix of Figure 5(b) contains the equilibrium constants of a solute determined in different solvents. The targets are vectors of solvent properties that may cause the variation in the equilibrium constants of solutes. TFA links the model in Equation (5) with the model in Equation (7). Apart from the targets with chemical meaning, the unity target, which is a vector whose elements are all equal to one, is always tested to account for the possible presence of an offset in the bilinear model.

Once the selection of targets is finished, the next step is assessing if they can be included in the model that describes the variation of the data set. Till this point in the modeling process, PCA has indicated how many real factors should be present in the model and has perfectly defined the data space by means of the score vectors. Any real factor used to replace the scores must belong to the space defined by these abstract vectors. Therefore, testing the goodness of a target is simply finding out how far the vector related to this potential factor is from the space defined by the score vectors.

From a geometrical point of view, target testing consists of projecting the target selected, called hereafter input target \((x_i)\), onto the scores space. The projected target, the so-called output target \((x_o)\), lies on the scores space. Figure 6 shows the process of target testing for a data set described with two factors. The two principal components define, in this case, a plane.

![Figure 6](image)

**Figure 6** Geometrical representation of the target testing process for a data set described by two factors.
The perfect target would give $x_i = x_o$. However, this equality is never fulfilled in practice due to the experimental error in both the data matrix and the target vector. As a consequence, a target is accepted when the input target is close enough to the output target, i.e. when the length of the vector $e_i$ (apparent error in the target) is small enough. The difference between analogous elements of $x_i$ and $x_o$ is related to the quality of the target; thus, the smaller the difference the better the target. Nevertheless, this observation alone is not reliable enough to decide whether a target must be accepted. Empirical methods, such as the SPOIL function, and statistical tests, such as an $F$-test that compares the error in the target with the error in the data matrix, have been proposed to decide more soundly the acceptance or rejection of a target.

After the target testing step, several targets have been confirmed as suitable candidates to build the real model of variation of the data set. From all the targets that passed this test, a number equal to the number of factors determined by PCA should be chosen. When the number of targets accepted exceeds the size of the model, the best among them are selected.

In the definite model, the targets accepted replace the loadings ($P^T$) by a matrix of weight coefficients associated with the real targets ($C^T$ for the model in Equation 6 and $A^T$ for the model in Equation 7), the close relationship between a PCA model and a real model should be recalled. Taking the LSER example in Equation (7) yields Equation (8):

$$TP^T = SA^T$$

where $S$ is the matrix whose columns are the solvent properties ($s_i$) accepted in the target testing step. This equation can also be written as Equation (9):

$$TY(Y^{-1}P^T) = SA^T$$

where

$$TY = S$$

$$Y^{-1}P^T = A^T$$

From Equation (10), where $T$ and $S$ are known, $Y$ can be calculated. Once $Y$ is known, $A^T$ can be calculated using Equation (11) and the real model is completed. The reproduction of the original data set, $D$, would be as shown in Equation (12):

$$D_{TFA} = SA^T$$

If $D_{TFA}$ and $D$ are sufficiently similar, i.e. the differences can be considered as due to experimental error, the real model proposed is suitable to describe the data set. When this does not happen, some targets in $S$ can be correlated and, then, new models with other accepted targets should be tried.

All the data sets that can be organized in matrices do not have the same features. This is clearly seen when the two data sets in Figure 1 are compared. The data set in Figure 1(a) is formed by voltammograms related to different samples. There is no loss of information if the order of the rows (samples) is exchanged. Figure 1(b) contains the data set obtained in the spectrometric monitoring of a kinetic process. If the rows of the data matrix, which are related to each reaction time, are organized differently, the information about the kinetic evolution is lost. Data sets like the latter describe dynamic systems and are often found in chemistry, e.g. high-performance liquid chromatography/diode-array detector (HPLC/DAD) data, or spectrometric monitoring of thermodynamic, thermal or any other parameter-dependent reaction. For these cases, there are some FA-based techniques, namely evolving factor analysis (EFA) and fixed-size moving window/evolving factor analysis (FSMW/EFA), which are designed to model the evolution of the factors in the data set. The evolution of these abstract factors is connected with the development of the chemical process.

EFA was first proposed by Maeder and co-workers to treat spectrometrically monitored equilibria and was afterwards applied to any other kind of data set coming from dynamic chemical processes, such as HPLC/DAD, kinetic transformations, or structural transitions.

The EFA method calculates the eigenvalues obtained from the PCA of gradually growing submatrices of the original data set, $D$ ($m \times n$). PCA is performed repeatedly in submatrices generated by increasing the size of the previous submatrix by one row. This size increase is performed from the top to the bottom of the original data matrix $D$ (forward EFA) and also in the opposite sense (backward EFA). Thus, forward EFA first carries out PCA on rows 1 and 2 of the data matrix, then on rows 1, 2, and 3 and so on until the final PCA on the $m$ rows of the whole data matrix is performed. Backward EFA starts by performing PCA on the rows $m$ and $(m-1)$, then adds the row $(m-2)$ to the analysis and so forth until the final PCA is carried out with the whole data matrix.

The EFA plot displays the evolution of the eigenvalues as the submatrix analyzed grows, i.e. as the evolutionary process in the data matrix goes from the beginning to the end (forward EFA) or vice versa (backward EFA). The log(eigenvalues) are plotted versus the row number of the last row included in the PCA or, better, versus the value of the variable responsible for the evolutionary process related to this row (e.g. a pH value in an acid–base equilibrium or a retention time in an HPLC/DAD
Figure 7 Construction of an EFA plot related to the spectrometric titration of a diprotic acid (simulated data). The continuous lines join the eigenvalues (circles) obtained in each PCA of forward EFA and the dashed lines connect the eigenvalues (squares) obtained in each PCA of backward EFA. EV stands for eigenvalue.

data set). Figure 7 shows the EFA plot related to a matrix formed by data coming from the spectrometric monitoring of the acid–base equilibria of a diprotic acid. Each row in the matrix is a spectrum collected at a certain pH value.

As PCA does, an EFA plot indicates the total number of components in the data set. The eigenvalues related to chemical components are clearly higher than the eigenvalues associated with noise. At the bottom of the plot, the many overlapping noise eigenvalues define a graphical threshold that can be considered the noise level of the system. All the eigenvalues above this limit are chemically significant. The total number of chemical components can be determined from the number of significant eigenvalues obtained in the last PCA performed in both forward and backward data analyses (i.e. with the results in the right and left extremes of the forward and backward EFA plot respectively). In the example of Figure 7, three chemical components, related to each of the species of a diprotic acid, are detected.

In contrast to PCA, an EFA plot also marks the zones of appearance and disappearance of chemical components. The appearance of a new species is detected in the forward EFA through the emergence of a new significant eigenvalue. Thus, when the row added to a certain submatrix includes a new chemical component, the different information introduced by this component will cause a significant increase in the ‘until then’ first noise eigenvalue. The chemical variable (e.g. pH, time, etc.) corresponding to the new row included in the analysis indicates the chemical conditions in which the new component appears. When performing backward EFA, the process is followed from the end to the beginning. Therefore, the presence of a new significant eigenvalue indicates the row, and consequently the chemical conditions, in which a component disappears. According to the forward EFA results in Figure 7, the two most protonated forms of the diprotic acid are present at pH 2, whereas the third one appears at a pH close to 5.5. Looking at the backward EFA plot, the most deprotonated form is still present at pH 10, the next one disappears at a pH close to 9 and the most protonated at a pH around 5.

The evolution of the eigenvalues in the forward and backward EFA is connected with the formation and decay curves of the chemical components present in the data matrix. When the appearance and disappearance of the chemical components are sequential, as in the example of Figure 7 and other reaction processes, or as in most of the chromatographic elutions, the suitable connections between the lines of the forward EFA plot and the backward EFA plot can provide abstract profiles related to the evolution of each of the chemical components in the data matrix. Thus, for a system with \( n \) components, the profile of the first component appearing is built connecting the line of the first eigenvalue of the EFA forward plot with the line of the \( n \)th significant eigenvalue of the EFA backward plot (related to the first compound disappearing); the profile of the second component connects the second eigenvalue in the EFA forward plot with the \((n-1)\)th eigenvalue of the EFA backward plot and so on. The zone of the matrix (rows) where the concentration profile of one compound shows values different from zero is the concentration window related to this compound (see Figure 8). The abstract profiles obtained with EFA are often used as a starting point in the iterative resolution methods described in sections 3 and 4 of this chapter.

The EFA method can be applied to both directions in the data matrix (i.e. the successive PCA can be performed in row- or column-wise growing submatrices of the original data matrix). In any case, the most useful results will always be obtained in the direction where the overlap of the different chemical components is less.

FSMW/EFA was proposed by Keller and Massart as a derivation of EFA. In contrast to EFA, FSMW/EFA
scans the original data matrix from top to bottom by performing PCA on “equally sized” submatrices. A new submatrix is built by removing the first row of the previous submatrix and adding the following row in the original data matrix, i.e. moving a window of a fixed number of rows one row downwards. The size of the window usually exceeds the number of chemical components by one, though more information can be obtained if FSMW/EFA is applied several times using different window sizes.\(^{(19)}\)

A local rank map, i.e. a graph with information about the number of significant principal components (chemical components) in each zone of the data matrix, is obtained by plotting the eigenvalues obtained in each PCA vs the variable responsible for the evolution of the process, as shown in Figure 9. In this plot, the noise level is also defined graphically by the zone in which the noise eigenvalues appear together. The emergence of one significant eigenvalue from the noise level zone indicates the presence of only one species in that zone; the presence of two significant eigenvalues defines the zone where two species coexist, three significant eigenvalues would detect the overlap of three species, and so on.

The local rank map obtained through the application of FSMW/EFA allows the detection of selective zones, i.e. zones where only one chemical component is present. The zones where only one significant eigenvalue is present are the selective zones of the species (the detection and location of these regions is essential in the resolution of a data matrix). In Figure 9, two selective zones are detected, one for the most deprotonated form of the diprotic acid and another for the intermediate form of this compound. FSMW/EFA also contributes to the detection of minor constituents. Actually, FSMW/EFA was initially proposed to deal with peak purity problems in chromatography. The local analysis of the data matrix and the clear graphical information help in the detection of minor species, although they are embedded under major constituents.

3 MULTIVARIATE CURVE RESOLUTION: GENERAL BACKGROUND

All the resolution methods were born as a tool to analyze multivariate experimental data coming from multicomponent dynamic systems.\(^{(20–27)}\) The common goal for all these methods is to mathematically decompose the global...
instrumental response into the pure contributions due to each of the components in the system. The use of such methods has become valuable when obtaining individual signals experimentally is not possible or when this process is too complex or too time-consuming.

The multivariate output of an experiment monitoring a dynamic process is organized in a double-structured matrix $D$ containing mixed information about the evolution of all the components present in the successive stages of the chemical process. The ultimate goal of the curve resolution (CR) methods is the decomposition of the initial mixture data matrix $D$ into the product of two data matrices $C$ and $S$, each of them including the pure response profiles of the $n$ mixture components associated with one of the directions of the initial data matrix (see Figure 10).

In matrix notation, Equation (13) gives the general expression valid for all CR procedures:

$$D = CS^T + E$$  \hspace{1cm} (13)

Figure 10  Two graphical views of the decomposition of a multicomponent data matrix: (a) as the product of the matrices including the pure response profiles; (b) as the sum of the products related to each pure contribution of the mixture components.

where $D$ ($r \times c$) is the original data matrix, $C$ ($r \times n$) and $S^T$ ($n \times c$) are the matrices containing the pure response profiles related to the data variation in the row direction and in the column direction respectively, and $E$ ($r \times c$) is the error matrix, i.e. the residual variation of the data set that is not related to any chemical contribution. $n$ is the number of chemical components in matrix $D$. Taking as an example a pH-dependent process monitored spectrometrically, the $C$ matrix would contain the pure concentration profiles of all the absorbing species and the $S^T$ matrix would be formed by their related pure spectra (see Figure 11). For the sake of simplicity, $C$ and $S^T$ are referred to as concentration profile matrix and spectra matrix, though this does not mean that the applicability of CR methods is restricted to this kind of chemical data.

The mathematical decomposition of a single data matrix is inherently affected by two sources of ambiguity: rotational ambiguity and intensity ambiguity. Whereas the former accounts for the possibility of reproducing correctly the original data matrix by using $C$ and $S$ matrices containing linear combinations of the true profiles, the latter warns about the possibility of having profiles equal in shape to the true ones, though different in magnitude. In other words, the correct reproduction of the original data matrix can be achieved by using response profiles differing in shape (rotational ambiguity) or in magnitude (intensity ambiguity) from the true ones.

The explanation of these two ambiguities is simple. The basic equation associated with CR methods, $D = CS^T$, can be easily transformed as shown in Equations (14–16):

$$D = C(TT^{-1})S^T$$  \hspace{1cm} (14)

$$D = (CT)(T^{-1}S^T)$$  \hspace{1cm} (15)

$$D = C'S'^T$$  \hspace{1cm} (16)

where $C' = CT$ and $S'^T = (T^{-1}S^T)$ describe the $D$ matrix as correctly as the true $C$ and $S^T$ matrices do, though $C'$ and $S'^T$ lack chemical sense. On the basis of the transformation shown in these equations, the mathematical formulation of the rotational ambiguity problem indicates that the possible solutions of a resolution method are as numerous as the $T$ matrices can be, i.e infinite. However, the inclusion of information related to the internal structure of the data (e.g. the presence of selective zones) and to their chemical properties in the resolution process often allows the suppression of this ambiguity or, at least, a large decrease in the number of feasible solutions.

When a system lacking rotational ambiguity is considered, the basic CR equation can still be rewritten as shown in Equations (17) and (18):

$$D = \left( \frac{1}{k} \right) CkS^T$$  \hspace{1cm} (17)

$$D = C'S'^T$$  \hspace{1cm} (18)

Figure 11  Results obtained after the application of a CR method on a data matrix coming from a pH-dependent process monitored spectrometrically. $ns$ means number of absorbing species.
where \( k \) is a scalar. The concentration profiles of the new \( C' = (1/k)C \) matrix have the same shape as the real ones, but are \( k \) times smaller, whereas the spectra of the new \( S' = kS \) matrix are shaped like the \( S \) spectra, though \( k \) times more intense. This ambiguity cannot be solved unless external information is introduced in the resolution process. Both rotational and intensity ambiguities are drastically diminished when several matrices (three-way data sets) are analyzed together.

The correct performance of the CR methods depends strongly on the internal features of the data set being analyzed, specially on selectivity and local rank. Regardless of the quality of each CR method, the two following conditions must be fulfilled if the true concentration profile and spectrum of each compound in the data matrix are to be recovered:

- The true concentration profile of a compound can be recovered when all the compounds inside its concentration window are also present outside.
- The true spectrum of a compound can also be recovered if its concentration window is not completely embedded inside the concentration window of a different compound.

The same formulation written above holds when, instead of looking at the concentration windows (windows of rows), the ‘spectral’ windows (windows of columns) are considered. The content of these theorems supports the fact that the goodness of the resolution result depends more strongly on the features of the data set (particularly those related to selectivity and local rank) than on the mathematical background of the CR method. Therefore, a good knowledge of the properties of the data sets before carrying out a resolution process provides a clear idea about the quality of the results that can be expected.

Seeing how close the PCA and the CR decomposition of a matrix are formally, it is not surprising that some CR methods, such as window factor analysis (WFA), or heuristic evolving latent projections (HELP), work with the abstract variables obtained by PCA in the resolution process. Some other methods transform initial estimates into real solutions projecting them iteratively onto the scores space, such as iterative transformation target factor analysis (ITTFA). Methods like multivariate curve resolution/alternating least squares (MCR/ALS) are linked to PCA because they often use initial estimates obtained by PCA-based techniques, such as EFA. Initial estimates can be also obtained by some other methods that use real variables, such as the simple-to-use interactive self-modeling analysis (SIMPLISMA) or the orthogonal projection approach (OPA). The CR methods can also be classified according to the data sets they can deal with. Thus, some methods are applied to the resolution of single matrices, such as HELP, WFA and ITTFA, whereas others can deal with two (generalized rank annihilation method, GRAM) or more matrices together (direct trilinear decomposition (DTD), parallel factor analysis (PARAFAC) and restricted Tucker models). Methods like MCR/ALS are adapted to one or more matrices.

4 NONITERATIVE AND ITERATIVE CURVE RESOLUTION TECHNIQUES

As mentioned in section 3, the goal of all CR is the decomposition of a mixture data matrix \( D \) into the product of the small matrices, \( C \) and \( S \), which contain profiles related to the evolution along the rows and along the columns of each pure component in \( D \). The noniterative resolution methods obtain \( C \) and \( S \) in one calculation step, whereas iterative resolution methods refine the profiles in \( C \), in \( S \) or in both matrices at each iterative cycle till an optimal solution is attained.

Noniterative resolution methods are the fastest, but they often require that the data set has certain features for them to be applied (e.g. WFA is meant to work with evolutionary data where each chemical compound has a unique maximum in its concentration profile). The user intervention is less, but usually more critical; wrong decisions cannot be changed in a one-step calculation method. Nevertheless, when the data sets fulfill the conditions needed by the CR method, these resolution procedures are a good alternative. The information provided by the global and local application of PCA to the data set is essential in most of these noniterative methods; thus, the quality of the final solutions depends basically on the correct determination of the total number of chemical components in the data set and on the construction of a reliable local rank map.

Within the group of noniterative resolution methods, HELP and WFA are probably the most well known. The HELP method is based on the local rank analysis of the data set and focuses on finding selective concentration and/or spectral windows. When these selective zones exist, the resolution of the system is clear. Thus, for a data set related to the spectrometric monitoring of a kinetic process (see Figure 1b), the row related to a selective reaction time directly provides the shape of the spectrum of the only component present at that stage of the reaction and the column related to a selective wavelength directly provides the kinetic concentration profile of the only absorbing compound at that wavelength. The main contributions of HELP have been offering a sophisticated graphical tool (the so-called datascope) to visually detect potential selective zones in the score plot of the data matrix and a statistical method to confirm the presence of
selectivity in the concentration and/or spectral windows graphically chosen. The statistical method is based on the use of an $F$-test to compare the magnitude of eigenvalues related to selective zones of the data set with eigenvalues related to noise zones of the data matrix, i.e. those where no chemical components are supposed to be present. The confirmation of a selective zone in the data set, which is actually a rank-one window in the data matrix, will then be obtained when no significant differences are found among the first eigenvalue of a noise-related zone of the data matrix and the second eigenvalue of the potential selective zone. The statistical part of the method can be negatively affected by the presence of nonchemical significant variations in the data, such as instrumental drift or nonrandom noise. It should be also noted that the application of this method requires that the data set has zero-component zones, which is easy in an HPLC/DAD data set (time windows with no compounds eluting are commonly found) but not so evident when a reaction monitoring is carried out (there is always some chemical compound in the reaction vessel), for instance.

WFA seems to have a wider field of applications than HELP and improved versions of the algorithm have recently been published. This method inspired in the rank annihilation evolving factor analysis (RAEFA) was proposed by Malinowski. WFA is applicable to data sets where the formation and decay of the compound profiles in one of the directions of the matrix (usually the concentration direction) is sequential, i.e. the compound appearing in the $n$th position disappears in the $n$th position. As a consequence, out of the concentration window of a certain compound all the other compounds in the data set are present.

WFA recovers each true concentration profile as follows (see Figure 12):

1. PCA of the original data matrix, $\mathbf{D}$.
2. Determination of the concentration window of each component.
3. PCA of a matrix, $\mathbf{D}^o$, where the rows related to the concentration window of the $n$th compound have been removed.
4. Calculation of the vector, $\mathbf{p}_n^{ot}$, which is the part of the spectrum of the $n$th component orthogonal to the spectra of the other components.
5. Recovery of the true concentration profile of the $n$th component using $\mathbf{p}_n^{ot}$ and $\mathbf{D}$.
6. Calculation of the spectra matrix $\mathbf{S}^T$ by least squares using $\mathbf{D}$ and $\mathbf{C}$.

The mathematical formulation associated with this method is not trivial and only a rough intuitive explanation will be given in this section. A detailed description can be found in the literature.

\[ \begin{align*}
\text{Conc. window} & \text{ $n$th component} \\
\mathbf{D} & = \mathbf{T} \quad \text{Rank $n$} \\
\mathbf{D}^o & = \mathbf{T}^o \quad \text{Rank $(n-1)$} \\
\mathbf{p}^T & \quad \text{ (c) recovery of the component of the spectrum of the $n$th component orthogonal to all the spectra in } \mathbf{D}^o; \mathbf{p}_n^{ot}; \text{ and (d) recovery of the concentration profile of the $n$th component.}
\end{align*} \]

\[ \begin{align*}
\epsilon & \quad \mathbf{p}_n^{ot} \\
\mathbf{D} & = \mathbf{P}^T \text{ (d) recovery of the concentration profile of the $n$th component.}
\end{align*} \]

WFA starts with the PCA decomposition of the $\mathbf{D}$ matrix into the product $\mathbf{TP}^T$ (remember Equation 1). In a general case, the $\mathbf{D}$ matrix can have $n$ components, i.e. rank $n$. The definition of the concentration windows for each component is carried out later using EFA (see Figure 8) or other methods. Steps 3 to 5 are the core of the WFA method and should be performed as many times as compounds are present in matrix $\mathbf{D}$ to recover every time one concentration profile of the $\mathbf{C}$ matrix.

For each component, a $\mathbf{D}^o$ matrix is built removing the rows related to its concentration window. Then, a PCA is performed and the product $\mathbf{T}^{op} \mathbf{p}^{ot}$ is obtained. Note that the $\mathbf{D}^o$ matrix has rank $n-1$ because the variation due to one of the components in the data set disappears when the related rows of the data matrix $\mathbf{D}$ are deleted. The loading matrices, $\mathbf{P}^T$ and $\mathbf{P}^{ot}$, describe the space of the $n$ pure spectra in $\mathbf{D}$ and the $(n-1)$
pure spectra in $D^p$ respectively. The rows in these loading matrices are actually “abstract spectra” and the real spectra can be expressed as a linear combination of them. The vectors either in $P^T$ or in $P_0^T$ could be interchangeably used to build these linear combinations if the information related to the removed component was present in $P_0^T$. Using these two loading matrices, it is possible to calculate a vector $P_0^T$, which is orthogonal to the $(n-1)$ $P_i^T$ vectors and which belongs to the space defined by $P^T$. This vector completes the set of vectors in $P_0^T$ and contains the part of the spectra of the removed component which is uncorrelated to the spectra of the other $(n-1)$ components in the data matrix. Using this vector with information exclusively related to the removed component, the true concentration profile of this compound can be calculated as shown in Equation (19):

$$D_p^c = c_n$$

The complete $C$ matrix is then obtained by appending row-wise the concentration profiles found for each compound in the $D$ matrix. Using the basic equation of CR methods, $D = CS^T$, the matrix of spectra, $S^T$, is obtained by least squares using the $D$ and $C$ matrices as shown in Equation (20):

$$S^T = (C^TC)^{-1}C^TD$$

The main drawbacks of WFA are the impossibility of solving data sets with nonsequential profiles (e.g. data sets with embedded profiles, for instance) and the dangerous effects of a bad definition of the concentration windows. Tackling this last point has been the main goal of recent modifications of this algorithm.\(^{(44)}\)

Despite the limitations associated with the noniterative methods, the information provided by local PCA performed in selected windows of the data matrix still inspires new algorithms for resolution, such as the very recent subwindow factor analysis (SFA), proposed by Manne et al.\(^{(47)}\) based on the comparison of matrix windows sharing one compound in common.

Iterative resolution methods are in general more versatile than noniterative methods. They apply to more diverse data (e.g. with sequential and nonsequential profiles, with different degrees of selectivity, etc.) and the previous knowledge about the data set (chemical or related to mathematical features) can be used in the optimization process. The main complaint about iterative resolution methods has often been the larger calculation times required to obtain the optimal results; however, improved fast algorithms\(^{(48,49)}\) and more powerful personal computers have overcome this historical limitation.

All iterative resolution methods refine the profiles in $C$, in $S^T$ or in both matrices at each step of the optimization process. The profiles in $C$ and/or $S^T$ are “tailored” according to the chemical properties and the mathematical features of each particular data set. The iterative process stops when a convergence criterion is fulfilled (e.g. a preset number of iterative cycles is exceeded or the lack of fit goes below a certain value).

Starting the iterative optimization of the profiles in $C$ or $S^T$ requires a matrix sized as $C$ or as $S^T$ with more or less rough approximations of the concentration profiles or spectra that will be obtained as the final results. This matrix contains the initial estimates of the resolution process. Though some authors are in favor of using random initial estimates,\(^{(50)}\) the most generalized opinion tends to recommend the use of nonrandom estimates to shorten the iterative optimization and to avoid the convergence to local optima different from the solution searched. If the initial estimates are either a $C$-type or an $S^T$-type matrix can depend on which kind of profiles are less overlapped, on which direction of the matrix (rows or columns) has more available information or simply on the will of the chemist. There are many chemometric methods to build initial estimates: some are especially suitable when the data consist of evolutionary profiles, such as EFA (see Figure 8), whereas some others mathematically select the purest rows or the purest columns of the data matrix as initial profiles. Within the latter, key set factor analysis (KSFA)\(^{(51)}\) works in the FA abstract domain and some other procedures, such as SIMPLISMA\(^{(26)}\) and OPA,\(^{(34)}\) work with the real variables in the data set and select the rows or the columns most representative and most dissimilar to each other. Besides the use of chemometric methods, a matrix of initial estimates can always be formed including the rows or columns of the data set that the researcher considers most representative for chemical reasons.

The general process in an iterative resolution method goes on with the optimization of the initial profiles with the help of some selected constraints. A constraint can be defined as any systematic feature in the data set (mathematical or chemical) translated into mathematical language. Therefore, the effectiveness of a constraint can change depending on the way it has been implemented and active research is in progress to optimize this point.\(^{(52–55)}\) In any profile, a constraint works by updating the elements that do not allow the fulfillment of a certain condition by some others that do. The use of constraints is optional and should be adapted to each particular data set. Small departures from the conditions imposed by some constraints are often allowed.

The most essential constraint in the resolution process is selectivity.\(^{(28)}\) The selective zones in a data matrix are those regions (row windows or column windows) where only one species is present, i.e. those with rank one; therefore, this is a constraint related to a mathematical feature. As mentioned in the brief comment about the
HELP method (see this section, above), the presence of selective zones for all the species in a data matrix eliminates the rotational ambiguity and ensures the recovery of the real response profiles of the chemical system. Local rank analysis methods, such as EFA and FSMW/EFA, are the most suitable techniques to detect and locate the selective zones of a system, as shown in section 2. The selectivity for one compound can be forced by setting to zero the elements of all the other response profiles in the selective regions of this compound.

The most frequent constraints related to chemical features of the profiles are described below:

1. Non-negativity. This constraint forces the values in a profile to be equal to or greater than zero and is applied to all the concentration profiles and to some experimental responses, such as ultraviolet (UV) absorbances.
2. Unimodality. This constraint allows the presence of only one maximum per response profile. It is applied to chromatographic peaks, to the concentration profiles of some chemical reactions and to some peak-shaped instrumental responses, such as voltammograms.
3. Closure. This constraint is applied to closed reaction systems for which the sum of the concentrations of all the species involved in the reaction or the sum of some of them is forced to be constant at each stage of the reaction. Actually, closure is a mass balance constraint.

A possible modification of some simulated profiles after the application of the constraints above is graphically shown in Figure 13.

Two of the most representative iterative resolution methods are ITTFA and MCR/ALS. Whereas ITTFA optimizes either the C profiles or the ST profiles in each iterative cycle, MCR/ALS modifies the profiles in both matrices in each step of the optimization. An additional difference is that ITTFA works by optimizing one profile at a time, whereas MCR/ALS refines together all the profiles in the constrained data matrices.

As the name suggests, ITTFA is based on TFA (see section 2). In TFA, some vectors (targets) are tested to see if they can be used to describe real sources of variation in the data set. These vectors have a chemical meaning and are perfectly characterized. In facing a resolution problem, the appropriate targets should be either potential concentration profiles or instrumental responses (spectra). However, in practice, the user can, at most, know exactly some of these real profiles and, in some situations, none of them. Therefore, the straightforward application of TFA to solve completely a resolution problem is not possible. ITTFA borrows two main ideas from TFA: the fact that the space of either the concentration profiles or the spectra can be perfectly known and the initial use of a target to finally obtain a true profile of the C or the ST matrix. Essentially, what ITTFA does is to modify a target until it lies on the real space of concentrations or spectra and fulfills the appropriate constraints. This process is repeated with as many targets as the data set has components.

It has been pointed out that ITTFA works by optimizing one at a time the profiles in either the C matrix or the ST matrix. The direction of optimization will depend on which information is considered most important by the chemist: e.g. in an HPLC/DAD run, getting the chromatographic peaks of each compound may be the priority; whereas in a process, monitoring the knowledge of the identity of the compounds involved (spectra) can be the main goal. The explanation given below holds for a data set where ITTFA is applied to obtain the profiles in the C matrix. Transposing the original data matrix, this process would be useful to get the profiles in ST. ITTFA gets each concentration profile following the steps below:

1. Calculation of the score matrix by PCA.
2. Use of an estimated concentration profile as initial target.
3. Projection of the target onto the score space.
4. Constraint of the target projected.
5. Projection of the constrained target.
6. Return to step 4 until convergence is achieved.

ITTFA starts performing PCA in the original data matrix, D. There is a formal analogy between the PCA decomposition, i.e. \( D = TP^T \), and the CR decomposition, i.e. \( D = CS^T \), of a data matrix. The scores matrix, T, and the loadings matrix, P, span the same data space as the C and the ST matrix do and their profiles can be described as abstract concentration profiles and abstract spectra respectively. This means that any real concentration profile of C belongs to the score space and can be described as a linear combination of the abstract concentration profiles in the T matrix.

The next step would be choosing approximate concentration profiles as targets. There are many ways to select these initial vectors; actually, any method used to provide initial CR estimates can be useful for this purpose. Historically, the vectors obtained after performing VARIMAX rotation onto the scores were used and also the needle targets (i.e. vectors with only one nonnull element equal to 1), which are the simplest representation of a peak-shaped profile.

The next step is the projection of the initial target (x1 in) onto the score space. The projected target (x1 out) belongs to the space of the real concentration profiles and, from
Figure 13 Performance of the constraints in the MCR/ALS method. (a) Selectivity. The solid line and the dashed line indicate the selective zones for compounds 1 and 2, respectively. On the right, the constrained matrix is shown. (b) Non-negativity, (c) unimodality and (d) closure: the normal line and the thick line show a response profile before and after the application of the constraint, respectively. (d) also presents the constrained concentration matrix.

a pure mathematical point of view, could be accepted to describe the data set. However, when this profile is plotted, the chemist may not like some of the features that present (e.g. negative parts, secondary maxima, etc.). When this happens, the projected target \(x_{1\text{out}}\) is modified by using the appropriate constraints. The application of constraints satisfies the chemical features demanded by the profile but, as a consequence of the modification of its elements, lifts the target from the score plane. The constrained target, \(x_2\), is projected again onto the score space and the new projected target, \(x_{2\text{out}}\), is constrained if necessary. The process goes on until the projected target makes sense from both mathematical and chemical points of view, i.e. until the constrained profile belongs to the score space or until it is very close to it. Figure 14 shows the ITTFA optimization of a chromatographic profile for a system with two compounds.

Once all the concentration profiles obtained are appended to form the \(C\) matrix, the \(S^T\) matrix can be calculated by least squares from \(D\) and \(C\) (see Equation 13).

MCR/ALS uses an alternative approach to find iteratively the matrices of concentration profiles and instrumental responses. In this method, neither the \(C\) nor the
and C practice. In contrast to ITTFA, MCR/ALS uses complete numbers of components is a usual and recommendable meter and resolution of the system considering different number obtained must not be considered a fixed parameter.

Return to step 3 until convergence is achieved.

1. Determination of the number of compounds in D.
2. Calculation of initial estimates (e.g. C-type matrix).
3. Calculation and constraint of the S^T matrix.
5. Return to step 3 until convergence is achieved.

The number of compounds in D can be determined using PCA or can be known beforehand. In any case, the number obtained must not be considered a fixed parameter and resolution of the system considering different numbers of components is a usual and recommendable practice. In contrast to ITTFA, MCR/ALS uses complete C- or S^T-type matrices during the alternating least squares (ALS) optimization. The two least-squares problems shown in Equations (21) and (22) are solved under restrictions such as non-negativity, unimodality or closure.

In these two equations the norm of the residuals between the PCA reproduced data, \( \hat{D}_{PCA} \), using the selected number of components and the ALS reproduced data using the least-squares estimates of C and S^T matrices, \( \hat{C} \) and \( \hat{S}^T \), is alternatively minimized keeping constant C (Equation 21) or \( \hat{S}^T \) (Equation 22). This is equivalent to the minimization of the least squares function \( (d_{ij} - \hat{c}_{ik}\hat{s}_{kj})^2 \), where \( d_{ij} \) are the experimental data and \( \hat{c}_{ik} \) and \( \hat{s}_{kj} \) are the current ALS estimations of the concentrations and spectra values (spectra \( i \), wavelength \( j \) and species \( k \)). The unconstrained least-squares solution of Equation (21) is given by Equation (23)

\[
\hat{S}^T = \hat{C}^+D_{PCA}
\]

where \( \hat{C}^+ \) is the pseudoinverse of the concentration matrix which for a full rank matrix gives Equation (24)

\[
\hat{S}^T = (\hat{C}^T\hat{C})^{-1}\hat{C}^TD_{PCA}
\]

and the unconstrained least-squares solution of Equation (22) is given by Equation (25):

\[
\hat{C} = D_{PCA}\hat{S}^T\hat{S}\hat{S}^{-1}
\]

Equations (23) and (24) are solved sequentially, i.e. from a given estimation of the concentration matrix C obtained in the previous cycle of the ALS optimization a new estimation of the spectra matrix \( S^T \) (Equation 24) is calculated, and from this a new estimation of the concentration matrix C is then calculated (Equation 26). These solutions may be constrained to fulfill particular requirements like non-negativity, unimodality and closure immediately after they are calculated using Equations (23) and (25) (i.e. before the next equation is applied). In this way, at each iteration of the ALS procedure, the solutions are improved not only from a least-squares sense but also to fulfill a particular set of constraints. Direct non-negative least squares solutions of Equations (21) and (22) can also be found using either the Lawson and the Hanson algorithm\(^{(58)}\) or recent faster modifications.\(^{(54)}\) Likewise, special algorithms have been proposed for the implementation of unimodality constraints.\(^{(55)}\) Initial estimates to start the ALS optimization can be obtained for C or for \( S^T \) matrices, using either pure variable detection methods, EFA-derived methods\(^{(59)}\) or previously known profiles. In the current implementations of the MCR/ALS method,\(^{(60)}\) different constraints may be selected for the C and the \( S^T \) matrix and, within each of those matrices, all or some of the profiles can be constrained.

Figure 14 (a) Geometrical representation of the optimization of a chromatographic profile by ITTFA from an initial needle target. The example represents a two-compound data set. Thick lines represent targets out of the score plane; thinner lines are targets on the score plane. (b) Evolution in the shape of the chromatographic profile through the ITTFA process.

\( S^T \) matrix have priority over each other and both are optimized at each iterative cycle. The general operating procedure of MCR/ALS includes:

1. Determination of the number of compounds in D.
2. Calculation of initial estimates (e.g. C-type matrix).
3. Calculation and constraint of the \( S^T \) matrix.
5. Return to step 3 until convergence is achieved.

The number of compounds in D can be determined using PCA or can be known beforehand. In any case, the number obtained must not be considered a fixed parameter and resolution of the system considering different numbers of components is a usual and recommendable practice. In contrast to ITTFA, MCR/ALS uses complete C- or \( S^T \)-type matrices during the alternating least squares (ALS) optimization. The two least-squares problems shown in Equations (21) and (22) are solved under restrictions such as non-negativity, unimodality or closure.

\[
\min_C \| \hat{D}_{PCA} - \hat{C}\hat{S}^T \| \quad (21)
\]

and

\[
\min_S \| \hat{D}_{PCA} - \hat{C}\hat{S}^T \| \quad (22)
\]
The convergence criterion in the ALS optimization is based on the comparison of the fit obtained in two consecutive iterations. When the relative difference in fit is below a threshold value, the optimization is finished. Sometimes a maximum number of iterative cycles is used as the stop criterion. This method is very flexible and may be adapted to very diverse real examples, as shown in section 6.

5 THREE-WAY RESOLUTION METHODS

The methods presented in previous sections are suitable to work with a data matrix and give results related to the two different directions of the data matrix, i.e. profiles related to the variation along the rows and along the columns of the data matrix. This is the reason why a data matrix is also called a two-way data set.

A data matrix is not the most complex data set that can be found in chemistry. Let us consider a kinetic process monitored fluorimetrically; at each reaction time, a series of emission spectra recorded at different excitation wavelengths are obtained. This means that we collect a data matrix at each stage of the reaction and if the goal is getting a picture of the global kinetic process, the matrices should be considered altogether. The information about the whole kinetic process should now be organized in a cube of data (tensor) with three informative directions, i.e. in a three-way data set. Another usual example is coupling data matrices from different samples that share all or some of their compounds, e.g. several HPLC/DAD runs. In this case, the third direction of the data set accounts for the quantitative differences among samples. Figure 15 shows both examples mentioned.

Though there is a clear gain in quality and quantity of information when going from two- to three-way data sets, the mathematical complexity associated with the treatment of three-way data sets can seem, at first sight, a drawback. To overcome this problem, most of the three-way data analysis methods transform the original cube of data into a stack of matrices, where simpler mathematical methods can be applied. This process is often known as unfolding. A cube of data sized \((m \times n \times p)\) can be unfolded in three different directions: along the row space, along the column space and along the third direction of the cube, also called the tube space. The three unfolding procedures give a row-wise augmented matrix \(D_r(m \times np)\), a column-wise augmented matrix \(D_c(n \times mp)\) and a tube-wise augmented matrix \(D_t(p \times mn)\), respectively (see Figure 16). When the rank analysis of the three augmented matrices is carried out, the number of components obtained for the three different directions (modes) of the data set may be the same or not. When \(D_r\), \(D_c\) and \(D_t\) have the same rank, the three-way data set is said to be trilinear and when their ranks are different from each other, the data set is nontrilinear. (Please note that this definition holds for by far most of the chemical data sets, except those for which phenomena of rank deficiency or rank overlap are present).\(^{61,62}\) The resolution of a three-way data set into the matrices \(X\), \(Y\) and \(Z\), which contain the pure profiles related to each of the directions of the three-way data set, changes for trilinear and nontrilinear systems, as can be seen in Figure 17. For trilinear systems, \(X\), \(Y\) and \(Z\) have the same number of profiles \((nc)\) and the three-way core, \(C\), is an identity cube \((nc \times nc \times nc)\) whose unity elements are placed in the superdiagonal. In this case, the three-way core is often omitted because it does not modify numerically the reproduction of the original tensor. Each element in the original three-way data set can be reproduced as follows:

\[
d_{ijk} = \sum_{f=1}^{nc} x_{if} y_{jf} z_{kf} \tag{27}
\]

Equation (27) is the fundamental expression of the PARAFAC model\(^{37–39}\) which is used to describe the decomposition of trilinear data sets.
Figure 16 Unfolding of a three-way data set into a row-wise data matrix, $D_r$, a column-wise data matrix, $D_c$, and a tube-wise data matrix, $D_t$.

Figure 17 Decomposition of three-way data sets. (a) With trilinear structure. The dashed core can be omitted and is a regular identity cube. (b) With nontrilinear structure. The core is necessary and has a different number of components in each direction.

For nontrilinear systems, the core $C$ is no longer a regular cube ($n_{cr} \times n_{cc} \times n_{ct}$) and the nonnull elements are spread out in different ways depending on each particular data set. $n_{cr}$, $n_{cc}$ and $n_{ct}$ hold for the rank in the row-wise, column-wise and tube-wise augmented data matrices respectively. Each element in the original data set can now be obtained as shown in Equation (28):

$$d_{ijk} = \sum_{f=1}^{n_{cr}} \sum_{g=1}^{n_{cc}} \sum_{h=1}^{n_{ct}} x_{if} y_{fg} z_{kh} c_{fgh}$$

Equation (28) defines the decomposition of nontrilinear data sets and is the underlying expression of the Tucker3 model.\(^{(40)}\)

Decompositions of three-way arrays into these two different models require different data analysis methods; therefore, finding out if the internal structure of a three-way data set is trilinear or nontrilinear is essential to ensure the selection of the suitable chemometric treatment.

In this section, the concept of trilinearity has been tackled as an exclusively mathematical matter. However, the chemical information is often enough to determine if a three-way data set presents this feature. How to link the chemical knowledge with the mathematical structure of a three-way data set can be easily seen with real examples. Let us consider the three-way data sets in Figure 15. If a data set is trilinear, $X$, $Y$ and $Z$ will have as many profiles as chemical compounds in the original data set and this number will be equal to the rank of the data set. For each chemical compound, there will be only one profile in $X$, in $Y$ and in $Z$ common to all the appended matrices in the original data set. In the HPLC/DAD example, the decomposition of the three-way array gives an $X$ matrix with chromatographic profiles, a $Y$ matrix with pure spectra and a $Z$ matrix with the quantitative information about each compound in the different chromatographic runs. In this case, a trilinear structure would imply that the pure spectrum and the pure chromatogram of a compound remain invariant in the different chromatographic runs. If the experimental conditions in the runs analyzed are similar enough, the UV spectrum of a pure compound should not change; however, run-to-run differences in peak shape and position are commonly found in practice. Assuming that the elution process of the same compound in the different runs yields always the same chromatographic profile does not make sense from a chemical point of view and, therefore, the data set should be considered nontrilinear. In the example related to the fluorimetric monitoring of a kinetic process, the decomposition of the original data set gives a matrix $X$ with pure excitation spectra, a matrix $Y$ with pure emission spectra and a matrix $Z$ with the kinetic profiles of the process. A trilinear structure would indicate that the shape of the excitation spectrum and the emission spectrum of a
compound does not change at the different reaction times of the kinetic process. This invariability of the spectra is an acceptable statement if the experimental conditions during the process are not modified. Therefore, this data set may be considered trilinear.

In practice, most of the systems are nontrilinear due either to the underlying chemical process (e.g. UV reaction monitoring coupling experiments with different reagent ratios) or to the instrumental lack of reproducibility in the response profiles (e.g. chromatographic profiles in different HPLC/DAD runs). Therefore, section 6 is mainly focused on the study of real examples lacking the trilinear structure.

Despite the higher abundance of nontrilinear data sets, many of the algorithms proposed to study three-way arrays rely on the assumption of trilinear structure. This is the case of GRAM,\(^{35}\) designed to work with two matrices, or its natural extension, DTD,\(^{36,60}\) which can handle larger data sets with more appended matrices. Both GRAM and DTD are noniterative methods and use latent variables to resolve the profiles in \(X, Y\) and \(Z\). When these methods are applied to nontrilinear data sets, the profiles obtained often belong to the imaginary domain. Iterative methods are also used in three-way data and the scheme followed in their application is the same as for a single data matrix, i.e. determination of number of components, use of initial estimates, application of constraints and iterative optimization until convergence. Most of the iterative algorithms are based on least-squares calculations. As for two-way data sets, three-way iterative methods are more flexible and can deal with more diverse data sets.

It has been commented that three-way resolution methods generally work with the unfolded matrices. Depending on the algorithm used, the three unfolded matrices are used or only some of them. As examples, the PARAFAC decomposition of a trilinear data set using the three unfolded data matrices and the resolution of a nontrilinear data set by applying the MCR/ALS method to only one of the unfolded matrices will be described.

The PARAFAC decomposition of a trilinear data set can be obtained by using a constrained least-squares algorithm.\(^{37-39}\) The steps of the method are listed below:

1. Determination of the number of chemical compounds (rank) in the original three-way array.
2. Calculation of initial estimates for \(X\) and \(Y\).
3. Estimation of \(Z\), given \(D_t\), \(X\) and \(Y\).
4. Estimation of \(X\), given \(D_t\), \(Y\) and \(Z\).
5. Estimation of \(Y\), given \(D_t\), \(X\) and \(Z\).
6. Return to step 3 until convergence is achieved.

The number of chemical compounds (rank) in the three-way array is estimated for the unfolded matrices in the three directions of the data set \((D_t, D_r, \text{ and } D_c)\). If the data set is really trilinear, the rank values should coincide unless situations of rank deficiency or rank overlap occur.

Since the original data set is decomposed into three matrices, \(X, Y\) and \(Z\), the initial estimates should be a pair of matrices sized as two of the matrices resulting from the decomposition. Any combination, e.g. \(X\) and \(Y\)-type matrices, and \(X\)- and \(Z\)-type matrices, is accepted. The initial estimates can be calculated using any of the methods explained for resolution of two-way data sets.

From the original data set and the two matrices proposed as initial estimates, e.g. \(X\) \((m \times nc)\) and \(Y\) \((n \times nc)\), the third matrix of the PARAFAC model, \(Z\) \((p \times nc)\), may be calculated. To do so, the unfolded matrix in the direction of the matrix to be calculated, \(D_t(p \times mn)\), is used (mathematical details related to this step are in the literature\(^{39}\)). In each iterative cycle, this operation is performed analogously to obtain \(X\) and \(Y\) and every time the suitable unfolded matrix, \(D_r(m \times np)\) or \(D_t(n \times mp)\), participates in the calculation. The constraints explained in section 4 may be optionally applied to the profiles in \(X, Y\) and \(Z\). The original three-way array is reproduced according to Equation (27) and the end of the iterative process arrives when changes in the fit among two consecutive iterations are small enough.

Three-way data sets have been presented as cubes of data formed by appending several matrices together. This means implicitly that all the data matrices in a tensor should be equally sized; otherwise, the cube cannot be constructed. Besides, the information in the rows, in the columns and in the third direction of the array must be synchronized for each of the layers of the cube, e.g. in the HPLC/DAD example, if the columns are wavelengths, all the runs should span the same wavelength range and if the rows are retention times, the elution time range should also coincide. In experimental measurements, it may not be easy or convenient to fulfill these two requirements. Actually, synchronization can be difficult when the parameter that changes in one of the directions of the array cannot be controlled in a simple manner and getting matrices equally sized may also be inconvenient if this condition forces the inclusion of irrelevant information in some of the two-way appended arrays. An example of difficult synchronization is the coupling of experiments related to UV monitoring of pH-dependent processes since pH variations may not be easily reproducible among experiments. The inconvenience of appending equally sized two-way arrays is evident when HPLC/DAD runs related to a mixture and to matrices of single standards are treated together; if the runs of standards should cover the same elution time range as the run of the mixture, most of the information in these standard matrices will be formed by baseline spectra which are not relevant for the resolution of the mixture.
When building a typical three-way data set is not possible, there is no need to give up the simultaneous analysis of a group of matrices that have something in common. Some methods, such as MCR/ALS, are designed to work with only one of the three possible unfolded matrices. This operating procedure greatly relaxes the demands to the two-way arrays that are treated together. Indeed, MCR/ALS requires only one common direction in all the matrices analyzed, i.e. in the previous examples, the wavelength range of the spectra collected (see Figure 18).

The MCR/ALS decomposition of the three-way data set shows the ability of this method to deal with nontrilinear systems. Whereas the profile of each compound related to the common order of the column-wise augmented matrix (spectra) is considered to be invariant for all the matrices, the unfolded \( C \) matrix allows the profile of each compound in the concentration direction to be different for each appended data matrix. This freedom in the shape of the \( C \) profiles agrees with the nontrilinear structure of the data array. The least-squares problems solved by MCR/ALS when applied to a three-way data set are the same as those in Equations (23) and (25); the only difference is that \( D \) and \( C \) are now augmented matrices. Though the operating procedure of the method has been shown in section 5, some particularities connected with the treatment of three-way data sets deserve a comment.

![Figure 18](image)

**Figure 18** MCR/ALS decomposition of a three-way data set formed by three appended matrices.

In the resolution of a column-wise augmented data matrix, the initial estimates can be either a single \( S^T \) matrix or a column-wise augmented \( C \) matrix. The column-wise concentration matrix is built by placing the initial \( C \)-type estimates obtained for each data matrix in the three-way data set one on top of the other. The appended initial estimates must be sorted as the initial data matrices are in \( D \) and must keep a correct correspondence of species, i.e. each column in the augmented \( C \) matrix must be formed by appended concentration profiles related to the same chemical compound. When no prior information about the identity of the compounds in the different data matrices is available, the correct correspondence of species can be known from the resolution results of each single matrix.

The same constraints used in the resolution of a data matrix can be applied to three-way data sets. Selectivity and non-negativity affect the spectrum and the augmented concentration profile of each species, whereas unimodality is applied separately to each of the profiles appended to form the augmented concentration profile. The closure constraint operates by applying the corresponding closure constant to each of the single matrices in the column-wise concentration matrix. Another constraint specific of three-way data sets is the so-called correspondence among species. In each single matrix of a three-way data set, the concentration profiles of absent compounds are set equal to zero after each iterative cycle.

Though MCR/ALS is specially relevant to cope with nontrilinear data sets formed by matrices of varying sizes, it can also work with trilinear data sets. Because of the inherent freedom in the modeling of the profiles of the augmented \( C \) matrix, the trilinear feature is introduced in the MCR/ALS method as an optional constraint. The application of this constraint is performed separately on the concentration profile of each species. Thus, the profiles appended to form the augmented concentration profile of a certain species are placed one beside the other to form a new data matrix and PCA is performed on it. If the system is trilinear, the score vector related to the first principal component must show the real shape of the concentration profile and the rest of principal components must be related to noise contributions. The loadings related to the first principal component are scaling factors accounting for the species concentration level in the different appended matrices. Therefore, the new single profiles will be calculated as the product of the score vector and their corresponding scaling factor. The constrained single profiles are finally appended to form the new augmented concentration profile. All of this process is shown graphically in Figure 19. In contrast to some other three-way resolution methods specially designed to work with trilinear systems, the
SOFT MODELING OF ANALYTICAL DATA

Figure 19 Application of the trilinearity constraint in the MCR/ALS method.

implementation of this constraint in MCR/ALS should not necessarily be complete, i.e. all or some of the compounds can be forced to have common profiles in the C matrix. This flexibility allows a more representative modeling of some real situations, like those of systems with trilinear profiles related to the evolution of chemical compounds and a free modeled profile related to an important background contribution.

The information in the third direction of the array, i.e. the Z matrix, is directly extracted from the augmented matrix C in MCR/ALS. This dimension of the data set is usually the smallest in size and is connected with scaling differences among the matrices appended. Since the S profile of one compound is common to all the appended data matrices, the area of the concentration profiles of this compound is scaled according to the concentration level of the species in each single data matrix. Thus, the profile of a compound in the Z matrix accounts for the relative concentration of a particular compound in each of the appended matrices and can be obtained from the ratio between the area of its concentration profile in a given matrix and the area related to the concentration profile of the same compound in a matrix taken as reference.

Since MCR/ALS has been proven to be a very versatile method to deal with any kind of three-way data set, this method has been used to work with all the diverse examples shown in section 6.

6 EXAMPLES OF APPLICATION

Different examples have been selected showing the possibilities of soft modeling methods in the analysis of chemical data. The first example refers to a chromatographic co-elution using LC/DAD. This is a typical example of analytical chemistry where the motivation of the data analysis covers most of the aspects analyzed in previous sections: estimation of the number of components coeluting in a chromatographic peak using FA-derived methods; estimation of the elution windows of each of these co-eluting peaks using EFA-derived methods; resolution of these components by means of multivariate resolution methods; and finally the eventual quantitation of these components. The second example will be the analysis of IR spectral data from multiple runs of an industrial process. In this case the goal of the data analysis is the development of a soft model explaining how the industrial process evolves, resolving the different components of the system and estimating the relative concentrations of the different constituents at any stage of the process from its time spectrum. The third example refers to the study and interpretation of thermodynamic and conformational transitions of polynucleotides using UV absorption and circular dichroism (CD) spectrometric methods.

6.1 Example 1: Chromatographic Co-elution Using Liquid Chromatography/Diode-array Detection

Soft modeling FA-based methods have been proposed for the analysis of unresolved peaks in LC/DAD and particular attention has been focused in the use of FA and MCR methods, like ITTFA, EFA, WFA, SIMPLISMA or HELP, have been used as qualitative tools for resolution of co-eluted peaks and peak purity, and they are not intended to provide fully quantitative information about the overlapped components. However if several chromatographic runs are simultaneously analyzed using MCR, relative quantitative information may be obtained similarly to three-way data analysis and second-order calibration methods. The key aspects for this quantitation to be possible are that the spectrum of the same chemical component in the different chromatographic runs does not change and, eventually, that the elution profile of a component in the different chromatographic runs also has the same shape and is synchronized. In case this second condition be not totally obeyed, resolution and quantitation of the co-eluted compounds is still possible, but the accuracy of the obtained solutions will depend on local rank and resolution conditions.

As an example of chromatographic co-elution, Figure 20 shows a three-dimensional plot of the data
matrix obtained in the co-elution of two pesticides, pirimicarb and 1-naphthol, using LC/DAD. Apparatus, reagents, chromatographic conditions and other experimental details are given in Tauler et al.\(^{64}\) Figure 21 shows the results of EFA using a fixed-size moving window of the data given in Figure 20. Along the experiment, two components were detected and distinguished from the noise level. The FSMW/EFA results suggested that the system might be resolved with few ambiguities since selectivity and local rank conditions were present. This is a common situation in chromatography, except for embedded peaks (one peak inside another\(^{29}\)). Embedded unresolved peaks can still be resolved when several chromatographic runs are simultaneously analyzed and at least in one of the runs, the local rank and resolution conditions are also achieved for that embedded component.\(^{65,66}\)

Application of MCR/ALS to the data of Figure 20, together with the data from the individual analyses of the two pesticides, gave the resolved pure spectra and elution profiles of Figures 22 and 23. Component 1 refers to pirimicarb, and component 2 refers to naphthol which elutes second. This resolution was obtained using non-negativity constraints for elution and spectral profiles and using unimodality constraint for the elution profiles. Each component is characterized by a pure spectrum equal in all the data matrices where this component is present. The pure spectra recovered (Figure 23) in the simultaneous numerical treatment were found to be equal to the pure spectra obtained in the individual chromatographic analysis of the pure analyte samples. In Figure 22, the two elution (concentration) profiles for each of the two components are given, one for the component in the pure analyte sample and the other for the same component in the unknown mixture.

Figure 20 Three-dimensional plot of the LC/DAD peak of the unresolved mixture naphthol–pirimicarb.

Figure 21 FSMW/EFA of the data given in Figure 20. During the experiment two distinctive components are clearly distinguished with an overlapped range between \(450 \times 10^{-3}\) and \(510 \times 10^{-3}\) min.

Figure 22 Resolved elution–concentration profiles of the components in the three samples simultaneously analyzed: (1a) pirimicarb in the pure analyte sample; (1b) pirimicarb in the mixture; (2a) naphthol in the pure analyte sample; (2b) naphthol in the mixture.

The resolution of the two co-eluted components in the unknown mixture was equal to 0.489.

Once the concentration profiles of the different components in the mixture are recovered using the proposed method, the concentration of the analytes in the samples can be estimated. If the conditions of linearity hold, the area under the concentration profile of a certain component is proportional to the concentration of this analyte. The ratio between these areas for a particular component
gives the ratio between the concentrations of that particular analyte in the different samples, recovering directly the relative quantitative information. If, in addition, in one or some of the experiments the concentration of the analyte is known, the concentration of the analytes in the unknown samples can be calculated also in absolute values. In this example, the method of quantitation is improved when the constraint of equal shape over the concentration profiles is applied (trilinear data).

In Table 1 a summary of the results obtained when different methods of quantitation are applied to the unresolved mixture of pirimicarb and naphthol (Figure 20) are given. For comparison, the results given first (method 1) correspond to those obtained by classical least-squares regression when the pure unit spectra of all the eluted components are given in the input. The analysis is performed only over the unresolved mixture data matrix. Whereas the results for pirimicarb are rather good, those for naphthol are poorer. The results of the simultaneous analysis of the data matrices obtained in the chromatographic analysis of an unknown mixture together with one or two pure analyte samples are also given. When the unknown mixture is analyzed together with these two samples, the results (method 2a) are better than before, although still with some error in the estimation of the pirimicarb concentration. When one of the two co-eluted components is considered an interferent and the unknown mixture is analyzed together with a pure analyte sample containing the other co-eluted component, the results (methods 2b and 2c) are worse, specially for pirimicarb with an error of 26% (method 2c). Conversely, when the constraint of equal shape in the elution profiles is added (method 3), the results of the quantitation are good in all the cases. When naphthol is considered an interferent and only the pure pirimicarb sample is included in the simultaneous analysis, the quantitation of pirimicarb is still very good (1% error). Although method 2 has the advantage that it did not require synchronization in the time order, it has the disadvantage that it requires more knowledge about the interferents to resolve the overlapped components in quantitative terms. Method 3 is the best choice for quantitation when interferents are present and it is closely related to second-order calibration and trilinear resolution methods. However, it requires the data to be trilinear, which is rather unusual in real chromatographic co-elution conditions.

The results of Table 1 show that MCR can be adapted to handle LC/DAD data of different complexity. For those cases where the elution of the components is not completely reproducible because of experimental or instrumental limitations, the method can still be used for quantitation, although now the error caused by the presence of unknown interferents not present in the known analyte samples will be higher. Other recent examples of application of the MCR method to chromatographic co-elution problems have proved the utility of the proposed method and have been extended to more difficult resolution problems. Examples are the resolution of mixtures of traces of herbicides and pesticides, in interlaboratory studies in the resolution of liquid chromatography/mass spectrometry (LC/MS) co-eluted peaks with common mass spectrometric ions, as well as in

### 6.2 Example 2: Infrared Spectral Data Analysis from Multiple Runs of an Industrial Process\(^{(69)}\)

Recent advances in process instrumentation and in data collection techniques have resulted in a rapid increase in the amount of data that can be acquired from chemical processes. Extracting the significant information from the data produced by modern instrumentation is in many circumstances a nontrivial task. The description and modeling of the evolution of a chemical process is important for both practical and economic reasons. In many of these cases multivariate calibration and regression methods\(^{(70)}\) cannot be applied because there is no previous information available to perform the calibration of the system. Examples of this situation in process analysis are abundant and include monitoring the evolution of chemical processes where one or more parameters are changed, like time, temperature, pH, the concentration of a reagent or any other parameter, and there is no previous quantitative information about the evolution of the process. The multivariate data acquired with spectroscopic probes produce continuous data which can be arranged in an ordered data matrix according to the variation of the parameter changed during the process. One way to address this problem is by CR methods.

In the case of process analytical chemistry\(^{(71)}\), the final goal is the estimation of the concentration of the constituents in the mixture change along the process and simultaneously the estimation of the unit responses (pure spectra) of those constituents. To have a meaningful solution from the CR decompositions it is necessary to make some assumptions about the signals obtained apart from their bilinearity, such as non-negativity, unimodality or closure. Taking advantage of the ordered structure of the process analysis data, EFA provides very valuable information concerning the windows of existence and relative importance of every component in the unknown mixtures existing at any time during the evolution of the process.

In addition, if several runs of the same industrial process are available and as usually at least one of the two orders is common between them (e.g. the scanned spectral range), the intensity ambiguities associated with the analysis of a single process run can be resolved in relative terms. Assuming that the same component in the mixture has the same pure spectrum in the different process runs, the simultaneous analysis of different process runs can give the correct relative amounts of the common components in the different mixtures analyzed in the different process runs at any particular stage of the process.

Data for the present example are spectra obtained from successive runs of an industrial chemical process. The spectra are evenly spaced in time, but may represent different elapsed times from beginning to end. The spectral intensities are stored in a matrix \(D\) with one spectrum per row. The dimensions of \(D\) are the number of spectra by the number of spectral channels (e.g. wavelength). The object is to determine the number of unique chemical components included during the full process run along with their pure spectra and concentration/time profiles. Eight different runs of the same industrial chemical process at different days of production were analyzed. Every run contained between 75 and 125 spectra, 795 in total, measured along a broad IR spectral range of 66 channels. An example of the data collected in one of the runs of the process is given in Figure 24. As seen from Figure 24, the spectra change with time, starting from a very weak and flat background absorption, increasing the absorption giving two main absorption bands at channel numbers 10–20 and 50–60 and a broader absorption band around channel number 30, and finally decreasing the absorption very fast on all those bands when the process is terminated. All the runs show a similar pattern but with slight differences between them in the timing and in the position of the maxima (shifting), which show that there should be also some differences in the chemistry of the different runs of the process.

As also seen in Figure 24, the background absorption and baseline can also change during the process and are different among different runs. Therefore some data pretreatment is needed. First, to account for the differences in the initial baseline absorption among different process runs, subtraction of the first spectrum...
of each run from the following spectra in the same run removes these differences. This is true because in the first spectrum only the baseline or initial background absorption is present and the spectral bands of interest for the process itself have not appeared yet. With this treatment the first spectrum in each run always will be zero. Second, to account for the changes in the baseline or background during a particular run, the first and second derivatives of the raw spectra are calculated. That pretreatment allows the minimization of the contributions which are constant along a particular spectrum (first derivative) as well as those contributions which produce constant slopes within every spectrum (second derivative). In Figure 25, the second derivative spectra of the data set of Figure 24 are given. Most of the baseline changes are now removed. Pretreatment, second derivative and subtraction of the first spectrum were all analyzed and also compared with the analysis of the raw experimental spectra without any pretreatment.

The estimation of the singular values related with noise is performed using the first channels of the second derivative spectra where no band is present (Figure 25). As mentioned before, in second derivative spectra, the background and baseline contributions to the data variance are considerably diminished. The singular values obtained in this narrow spectral range are estimated for all the process runs together, to include the variations between process runs. At the same time, the singular values of the complete data set comprising the 64 channels of measurement, the process runs individually, and all together, were also calculated. In the comparison (Table 2) it was taken into account that the dimensions of the data matrix in one case and another were not the same and therefore the reduced singular values were used.

When the complete set of runs and spectra were analyzed, the maximum number of contributions associated with different chemical contributions was estimated as two or three, since the value of the third singular value is similar to the first singular value associated with the noise in the nonabsorbing parts of the spectra. When the analysis was performed over the individual process runs, it was found also that the number of chemical contributions was between two and three. The number of components obtained in this way was only a first estimation to start the resolution procedure. The number of three components was finally confirmed from the results of EFA and of the ALS optimization procedures (see below).

Figure 26 shows the spectra shown in Figure 25 recalculated using PCA. The principal components used in that reproduction are the three more significant found by the PCA of the whole augmented data matrix. As seen by comparison of Figures 25 and 26, most of the dominant spectral features are described by the three principal components (albeit obtained in the analysis of the 795 spectra without any pretreatment).

Figure 26 Reproduced second derivative spectra of the process run given in Figure 24 using three principal components.
of the eight different runs of the process, each one with 66 channels). Noise filtering is also achieved in this way and very little information is lost by considering only these three components. If only two components are considered a poorer reproduction of the original data is observed and if four components are considered very little improvement is achieved. The standard deviations of the residuals between the eight-run experimental matrix and the reproduced matrix considering two, three and four principal components are given in Table 3.

In Figure 27 an example of the plot of the concentration profiles obtained by EFA when applied to one run of the process is given. From EFA, three components were detected and differentiated from the other contributions. The fourth and fifth components emerged significantly from the error contributions only at the very end of the process when the reaction was terminated and therefore not of interest for the present study. Similarly, the EFA of each of the eight other process runs provides an initial estimation of the concentration profiles of the components in each process run. These concentration profiles were used as initial values in the ALS optimization. They can be used in the individual analysis of each set of data, or better, to build up the initial estimation of the augmented concentration matrix to be used in the simultaneous analysis of the eight runs of the process.

Although each process run was extensively analyzed individually, the results presented here refer only to those obtained in the simultaneous analysis. These solutions were improved by the added constraint of equality of spectra between process runs. The alternating and constrained least-squares optimization method was applied to the augmented data matrix containing the eight runs of the process arranged in the following three forms: without any pretreatment; with the first spectrum of each run subtracted; and with the second derivative augmented data matrix. The concentration matrix used initially in the optimization was the augmented concentration matrix containing the concentrations obtained in the individual EFA of each run. Of the three arrangements of the data matrix, the one which gave better results is the second case where the spectra of each run were corrected by subtracting the first spectrum of the same run. The reason for the better results in this case is that the subtraction of the first spectrum of each run removes the arbitrary offset between data from different process runs and that the non-negativity constraint can also be applied over the unit pure spectra. Conversely, when the optimization is performed over the second derivative spectra the non-negativity constraint is lost and it cannot be applied over the unit spectra. While the results are still in agreement with those obtained with the subtracted data matrix, the shapes of the recovered concentration profiles and pure spectra are less reliable. Of the three cases, the poorest results were obtained when no pretreatment was performed. The reason for this degradation of the resolution is because in that case the effects of the baseline (background absorption) between process runs and within process runs is rather high and the optimization is more difficult. In order to summarize the large amount of calculations performed during the work, only the results obtained in the simultaneous analysis of the eight runs of the process will be given. In the ALS optimization of the complete data set, the number of three components was again reconfirmed. If another number of components is considered, not only is the fit worse (see Table 3) but also the shapes of the recovered unit spectra and concentration profiles do not make chemical sense.

  * Standard deviation of the residuals between the experimental data matrix and the PCA reproduced data matrix.
  * Standard deviation of the residuals between the PCA reproduced data matrix and the calculated data matrix using the MCR/ALS optimized set of pure spectra and concentration profiles given in Figures 28 and 29.
  * Standard deviation of the residuals between the experimental data matrix and the calculated data matrix using the MCR/ALS optimized set of pure spectra and concentration profiles given in Figures 28 and 29.

![Figure 27 Initial concentration changes estimated using EFA of a single process run.](image)
Figure 28 shows the concentration profiles obtained in the analysis of the eight runs of the process after applying the constrained ALS optimization. Component one rises very fast at the beginning of the process, decreases a little and then keeps stable until the process is terminated. Component two is present except in process run 8, and always shows the same pattern of growth. The reason why this component does not appear in process run 8 is because the data analyzed pertain only to the first part of the process before it became present in appreciable concentrations. Component three does not appear at appreciable concentrations in all the runs. It is nearly nonexistent in process runs 1, 2 and 3, but it is the dominant contribution in process runs 4, 7 and 8.

The two constraints applied on the shape of the concentration profiles, non-negativity and unimodality, have an important role during the optimization. It was a little more difficult to handle the unimodality constraint because it has to account also for the small random oscillations and changes in the concentration of the components during the process; this means that although the global shape has to be unimodal and smooth, locally some small oscillations of the unimodality condition have to be allowed.

Figure 29 gives the pure spectra of the three common components deduced from the analysis of the eight runs of the process with the ALS optimization procedure applied to the augmented data matrix describing the eight runs of the process. The shapes obtained for these three unit spectra explain very well the changes observed in the shapes of the raw process experimental spectra of every run. For instance the first component only has the band around channels 50–60; this is in agreement with the first experimental spectra of every run which only show that band. Conversely, the second and third components have two bands approximately in the same locations but shifted between them. The strong absorption around channels 10–20 is more important for the third component than for the second, but the latter becomes the dominant contribution in some experiments. This is in agreement with what is observed from the detailed comparison of the spectra of the different runs. Moreover, the recovered pure spectra show a different baseline as a consequence of the observed baseline changes in the experimental spectra.

When the analysis is performed using the second derivative spectra the results are very similar to the ones given in Figures 28 and 29 but with a poorer description of the concentration profiles in some parts of the process, especially for component 2 in the first three runs. The reason for this degradation of the resolution is that the non-negativity constraint cannot be applied over the second derivative unit spectra. The non-negativity constraints applied over both the concentrations and unit spectra imply that the raw spectra contain only positive values, which is not always the case; therefore in the presence of negative absorbance the model will not be correct.

6.3 Example 3: Interpretation of Thermodynamic and Conformational Transitions of Polynucleotides

Nowadays, the experimental monitoring of biochemical processes is relatively straightforward due to the instrumental techniques and data acquisition systems available to the researcher. The typical output of an instrument used in monitoring the evolution of a process according
to the variation of a certain chemical variable consists of arrays of data (e.g. spectra) recorded at certain stages during the reaction (e.g. pH values, temperature, solvent polarity, etc.). These data can be organized in a data matrix, where the rows contain the instrumental responses and the columns reflect the relationship between the variation of the chemical variable and the evolution of the concentration of the species in the process. Despite the availability of such experimental data, univariate monitoring is still widely used in many chemical fields, such as biochemistry. Traditional biochemical studies tend to focus either on obtaining structural information under fixed conditions (e.g. physiological conditions) or on studying dynamic processes by recording univariate measurements (e.g. melting studies using single-wavelength absorbance readings).

Experiments conducted with small molecules have been traditionally interpreted by applying classical iterative least-squares methods based on the refinement of a postulated chemical model to obtain the optimal fit to the experimental data.\(^{(73)}\) This approach is often applied to the data coming from the spectrometric monitoring of chemical equilibria and is also known under the name of global analysis.\(^{(74)}\) The clear understanding of these simple equilibria allows the following assumptions in the process of model building: the fulfillment of the mass action law (i.e. the validity of a fixed equilibrium constant throughout the reaction); and the one-to-one correspondence between instrumental response and chemical species.

Nevertheless, most of these procedures are unable to interpret many biochemical processes due to the macromolecular nature of many biomolecules (e.g. polynucleotides, proteins, etc.) that causes a more complex evolution of the processes. The inapplicability of the classical methods can be explained by:

1. The existence of polyelectrolyte effects. The mass action law is no longer valid when either important changes in the electric field on the surface of the macromolecule or other effects related to conformational transitions modify the tendency of analogous sites to react. If this happens, Equation (29) gives

\[
\log K = f(\alpha) \tag{29}
\]

where \(\alpha\) denotes the extent of the reaction. Mathematical expressions which might model this effect cannot be devised since no information concerning its existence and its pattern (i.e. linear or nonlinear) for an unknown macromolecular process is available beforehand.

2. The existence of conformational transitions. Macromolecular biomolecules can show conformational transitions associated with a chemical reaction or with a spatial rearrangement of the molecule due to physical reasons. If the latter phenomenon occurs, the number of structural species will exceed the number of chemical species and the assumption of a one-to-one correspondence between chemical species and spatial configurations will be erroneous.

Of these techniques available for analyzing multivariate data sets, the self-modeling CR methods are the most appropriate for the analysis of evolutionary chemical processes when neither models nor prior information about the number and identity of the species involved are available, as is the case with biomacromolecular equilibria.

To illustrate the usefulness of the soft-modeling CR methods in the interpretation of biomacromolecular processes, the spectrometric (UV and CD) study of the acid–base behavior of the homopolynucleotides poly(uracylic acid) (polyU),\(^{(75)}\) poly(cytidylic acid) (polyC),\(^{(76)}\) and poly(adenylic acid) (polyA) in dioxane–water (30% v/v) is shown by way of example. Information about the identification and evolution of the chemical species, the existence and pattern of the polyelectrolyte effect and the conformational transitions associated with the studied reactions is presented. The solvent effect on these equilibria can be determined by comparing the results obtained in the hydroorganic mixture with those previously reported in aqueous solution using the same resolution method.

All the experiments were carried out in a dioxane–water (30% v/v) mixture. This hydroorganic mixture is often employed in biocoordination studies to emulate low-polar biological microenvironments.\(^{(75,77,78)}\) See the references for experimental details of these studies.

6.3.1 Concentration Profiles and Pure Unit Spectra of the Individual Species Involved in Acid–Base Equilibria

The number of species involved in each acid–base equilibrium and the initial estimates were determined using EFA. The acid–base equilibria of polyC and polyU were explained with two species, related to the protonated and the deprotonated species, whereas the polyA protonation process needed three species to be described. Figures 30 and 31 show the concentration profiles and spectra obtained in the MCR/ALS optimization for the three polynucleotides from the UV and CD titrations, respectively. The agreement between the distribution plots obtained with both spectrometric techniques for the same polynucleotide protonation process reflects the reproducibility of the experimental work and the good performance of the MCR/ALS method on this kind of biochemical data.
6.3.2 Detection and Description of Conformational Transitions

The concentration profiles diagram obtained with ALS provides complete information about the evolution of all the species present in the acid–base equilibria. This includes transitions between chemical species which do not involve changes in the spatial structure of the molecule, conformational changes associated with the proton uptake process and changes in the spatial configuration of a single chemical species which do not alter the protonation state of the molecule. Identifying which kind of transition takes place and which conformations are involved depends on the chemical knowledge about the process being analyzed. polyU, polyC and polyA are good examples of the three transitions mentioned above.

Chemical literature on polyU generally accepts the existence of random coil structures related to both protonated and deprotonated species. This is confirmed by the low ellipticities in polyU experiments compared with the ellipticities obtained for polyC and polyA experiments (Figure 31). The similar shape of the UV and CD spectra related to poly(UH) and poly(UH'), where the shift between their absorption maxima is the main difference, is in agreement with the hypothesis of a protonation process without conformational changes.

Literature studies of the polyC structure in aqueous solution suggested three different chemical species and conformations depending on the protonation form of the molecule, namely a single-helical deprotonated polyC, a double-stranded helical half-protonated [poly(C) · poly(CH+)'] and a fully protonated random coiled poly(CH+). Only two species were detected when this equilibrium took place in the hydroorganic mixture because of the narrower pH working range, limited by the precipitation of the charged polynucleotide at more acidic pH values. The most plausible identification of the two existing species includes the presence of the deprotonated and half-protonated polyC species. Apart from the similar shape of the spectra and the similar pH

Figure 30 MCR/ALS results from UV titrations in dioxane–water (30% v/v): concentration profiles and UV spectra related to the polyU–H, polyC–H and polyA–H systems. ε values are molar absorptivities.
region of existence of the species presented in Figures 30 and 31 and those found in aqueous solution, the absence of the characteristic decrease in the CD ellipticities associated with a helix to random coil transition, and the more favorable situation of a charged species partially stabilized with the formation of an interstrand hydrogen bond \( N\text{--H}^+ \cdot \cdot \cdot N \) in comparison with a species with a net charge \( \text{NH}^+ \) in a low-polar solution, support the identification proposed. Thus, the \( \text{polyC--H} \) system is a good example of acid–base equilibrium with a conformational change associated with the proton uptake process.

\( \text{PolyA} \) behaves in a way which is somewhat more complex than that of the two previous polynucleotides. Though the single-helical conformation of deprotonated \( \text{polyA} \) and its first transition to double-stranded protonated \( \text{polyA} \) is widely accepted, different conformational transitions between double-helical configurations of the protonated polynucleotide have also been proposed.\(^ {81–83} \) Figures 30 and 31 show three different species associated with the \( \text{polyA--H} \) system in the dioxane–water mixture. The similar shape of the two species occurring at more acidic pH values seem to identify them as different double-helical protonated configurations, whereas the species present at higher pH values can probably be attributed to the single-helical deprotonated \( \text{polyA} \). The transition between the deprotonated and the first protonated species, \( \text{poly(AH}^+)1 \), is associated with the proton uptake process, and therefore very reproducible. The transformation between the two protonated forms, \( \text{poly(AH}^+)1 \rightarrow \text{poly(AH}^+)2 \), presents more irregular concentration profiles owing to the lack of chemical reaction and to the probable time-dependency of the process.\(^ {83} \) Nevertheless, CD and UV spectra show coherent hyperchromism and hypochromism, respectively, when going from \( \text{poly(AH}^+)1 \) to \( \text{poly(AH}^+)2 \). Such a phenomenon could be explained by the gradual minimization of the electrostatic repulsion of neighboring phosphate groups due to the increase in the stabilizing electrostatic interactions between the negative charges of these groups and the protonated sites of the adenine bases as the protonation proceeds. Such a stabilizing effect would probably allow the formation of a more compact

---

and ordered structure with the phosphate groups occurring closer together and with a consequent stronger base stacking.

The presence of highly ordered polymeric structures could be confirmed by comparing the polynucleotide spectra with the spectra of their respective cyclic nucleotides, as shown in Figure 32. The marked hyperchromism in the CD spectra and hypochromism in the UV spectra of polyA and polyC with respect to cyclic adenosine monophosphate (cAMP) and cyclic cytidine monophosphate (cCMP) indicate a significant stacking in both polynucleotides and, therefore, the existence of ordered structures. The slight differences in terms of intensity between the polyU and cyclic uridine monophosphate (cUMP), and their respective low ellipticities compared with the other two previous cases, support the hypothesis of random structure for this polymer.

6.3.3 Existence and Pattern of Polyelectrolyte Effect

Once the species in the polynucleotide protonation process are identified, the equilibrium constant of this reaction can be properly evaluated. The distribution plot obtained by applying the MCR/ALS method provides an estimation of the concentration values of all the protonated and the deprotonated species for each pH measured. A log $K$ value may be then calculated for each titration point, bearing in mind that a fixed log $K$ value for each functional site of the polynucleotide during the whole protonation process cannot be obtained unless no polyelectrolyte effect exists. Plotting the log $K$ values versus their corresponding protonation degrees ($\alpha$) is a graphical way of studying both the existence and the pattern of a polyelectrolyte effect. If this effect is revealed, the so-called apparent constant ($K_{\text{app}}$) of analogous sites of the polynucleotide changes as the protonation process advances and the log $K$ value usually given is not a thermodynamic constant, but an intrinsic constant ($K_{\text{int}}$) defined as the extrapolated $K_{\text{app}}$ value for a protonation degree equal to zero, i.e. for the theoretical point where no effects of neighboring protonated sites are present.

Bearing in mind that the equilibrium process followed is the protonation of the site in the monomer unit of the macromolecule, the concentration of the polynucleotide
is expressed as moles of monomer per volume unit and, therefore, \( K \) is defined by Equation (30):

\[
K = \frac{[\text{protonated monomer}]}{[\text{deprotonated monomer}] [H^+]} \quad (30)
\]

and consequently, \( \alpha \) is given by Equation (31):

\[
\alpha = \frac{[\text{protonated monomer}]}{[\text{total monomer}]} \quad (31)
\]

In the expressions below referring to the protonation constants of each polynucleotide, the names between brackets indicate the form of the macromolecule where the protonated or deprotonated monomers are placed.

Figure 33 shows in thick lines the \( \log K \) versus \( \alpha \) plots for polyU, polyC and polyA in dioxane–water (30% v/v). The plots include the theoretical lines obtained after the polynomial fitting of the experimental (\( \alpha, \log K \)) values. The related equations \( \log K = f(\alpha) \) can be found in Table 4.

According to the identification of species in the MCR/ALS resolved distribution plots, the polyU protonation constant may be determined as shown in Equation (32):

\[
K = \frac{[\text{poly(U} - \text{H})]}{[\text{poly(U}^-)] [H^+]} \quad (32)
\]

No polyelectrolyte effect has been detected and, therefore, a thermodynamic protonation constant can be given for all the analogous protonation sites in the macromolecule. The absence of polyelectrolyte effect is probably due to previously detected random coiled structures associated with the protonated and the deprotonated species. These disordered structures are more flexible and allow spatial rearrangements of the macromolecule to minimize the between-sites effect during the protonation process.

The polyC protonation constant has been calculated using Equation (33):

\[
K = \frac{[\text{poly(C)} \cdot \text{poly(CH}^+) \cdot \text{poly(C)}]}{[(\text{poly(C)} + \text{poly(C)} \cdot \text{poly(CH}^+) \cdot \text{poly(C)})/2] [H^+]} \quad (33)
\]

Please note that the \([\text{poly(C)} \cdot \text{poly(CH}^+)\]) concentration is always divided by two when included as protonated and deprotonated forms due to the existence of one protonated base and one deprotonated base per base pair. There is a nonlinear pattern in the polyelectrolyte effect owing to the cooperative action between the protonation process and the formation of the double-stranded helical structure. Thus, the formation of this helix stabilizes the protonated base because of the interstrand hydrogen bond N–H⁺⋯N and, at the same time, this base pair arrangement is responsible for the growth and stabilization of the helical structure. As the protonation process advances, the intensity of the positive polyelectrolyte effect decreases, becoming negative for \( \alpha_p \) values higher than 0.3 because the increase of charge density in the macromolecular structure means that the repulsive effect between the protonated sites is more important than the stabilization caused by the formation of the double-helical structure.

The equation related to the polyA protonation process is given by Equation (34):

\[
K = \frac{([\text{poly(AH}^+1}] + [\text{poly(AH}^+2])}{[\text{poly(A)}][H^+]} \quad (34)
\]

d Numbers in parentheses are the errors associated with the last numeral.

e Results in aqueous solution are taken from Casassas et al.\(^{60}\) for polyU, Casassas et al.\(^{84}\) for polyC, and Casassas et al.\(^{11}\) for polyA.

f log K values for polyC and polyA are always intrinsic constants.

A linear positive polyelectrolyte effect caused by the stabilizing electrostatic interactions between the negatively charged phosphate groups and the protonated adenine sites is shown. The difference between the polyelectrolyte effect patterns of polyC and polyA depends on the role of the protonation sites in the formation of the double-stranded helix of the polynucleotide. PolyC protonated sites are responsible for the formation of one of the interstrand hydrogen bonds, whereas polyA protonated sites, though having a positive effect on the stabilization of the double-helical structure because of the minimization of the electrostatic repulsion of the phosphates, do not participate directly in the interstrand hydrogen bonding.\(^{82}\) Thus, a nonlinear pattern of the polyelectrolyte effect can in all likelihood be attributed to the presence of a cooperative mechanism associated with the protonation process, as occurs in polyC, whereas the more common linear pattern would appear to be caused mainly by purely electrostatic interactions, as shown in polyA and in other simpler polyelectrolytes, such as polycrylic acid.

A good agreement between the numerical values of polyU and of cUMP protonation constants and between the intrinsic protonation constant of polyC and the protonation constant of cCMP is shown, the slight differences between the values of \(K_{\text{polyU}}\) and \(K_{\text{cUMP}}\) being due to hindrance effects (see Table 4). No such agreement is noticed when the cAMP protonation constant and the polyA intrinsic protonation constant are compared. The significantly lower value of the cAMP protonation constant can probably be explained by the absence of the positive
influence of the surrounding phosphate groups, present on the protonation of all the adenine sites of polyA, on the protonation process of the cyclic nucleotide, cAMP.

6.3.4 Solvent Effect on the Acid–Base Equilibria of Polynucleotides

The acid–base equilibria of polyA, polyC and polyU were also studied in aqueous solution.\(^{80,81,84}\) The comparison of the results obtained in water with those obtained in dioxane–water (30% v/v) allows the inference of solvent effects on the protonation processes of the polynucleotides. The system dioxane–water was used because, in comparison with some other hydroorganic mixtures, it provides a larger decrease of polarity with the inclusion of smaller amounts of organic cosolvent. No experiments were performed at dioxane proportions higher than 30% (v/v) because some of the polynucleotides studied presented precipitation phenomena.

When comparing the experiments mentioned above, a general observation is the greater instability of charged macromolecular structures in the hydroorganic medium. Indeed, some species detected in aqueous solutions are apparently not formed in the lower-polar medium because the macromolecule is precipitated at suitable pH values. This is the case for the fully protonated poly(CH\(^+,\)) whose formation involves the appearance of two net charges in solution, one from the new protonated site and the other from the breaking of the interstrand hydrogen-bonding N–H\(^+\)...N. The precipitation of the macromolecule from dioxane–water solution also takes place for the protonated polyA at pH values lower than 4 and this prevents the formation of other postulated double-helical configurations at more acidic pH values. Disordered charged structures, such as deprotonated polyU, are more stable than ordered forms in dioxane–water solution due to the greater ability of the macromolecule to reach spatial arrangements suitable for accommodating the net charges.

All the species detected in dioxane–water (30% v/v) are present in water with the same spatial structure. The only difference is the formation of more relaxed configurations in the dioxane–water mixtures because of the weakening of the base stacking interactions caused by the low-polar solvents.

The polyelectrolyte effect, if absent or linear, maintains the same behavior in both solvents studied, as shown in Table 4 and in Figure 33. Thus, the polyU acid–base behavior does not present a polyelectrolyte effect either in water or in the working dioxane–water mixture and the only difference between the polyU equilibrium in both media is the higher value of the protonation constant in the hydroorganic mixture owing to the lower stabilizing effect of this low-polar solvent on the negatively charged deprotonated polynucleotide. Linear models with fairly similar slopes describe the polyelectrolyte effect associated with the polyA protonation process in hydroorganic and in aqueous solutions. Nevertheless, there is not enough information to determine whether the small difference between slopes is due to the intrinsic similarity of the polyelectrolyte effects in both media or whether the stabilizing effect of the inert salt counterions around the negatively charged phosphates conceals the real solvent effect on the polyA protonation process. To clarify this point, it would be necessary to work at lower ionic strengths.

There is a clear solvent influence on the pattern of the polyelectrolyte effect when a cooperative mechanism is involved in the polynucleotide protonation process, as can be seen in the polyC protonation process. Though not visible in Figure 33, where only the mathematically fitted positive polyelectrolyte effect is shown, there is a change in the sign of the polyelectrolyte effect associated with the polyC protonation process in both water and water–dioxane solutions.\(^{76}\) Solvent effect is first noticed in the ranges of existence of the positive and the negative polyelectrolyte effects. Whereas the change of sign appears in \(\alpha\) values around 0.3 in the hydroorganic solution, this negative behavior is not seen until \(\alpha\) values higher than 0.5 in water. The greater stability of charged structures in water explains why the negative polyelectrolyte effect does not appear in this solvent until the breakdown of the stable double-stranded helical structure takes place, whereas an increase in the charge density of the double-stranded helix is enough to change the tendency of the polyelectrolyte effect in less polar media. The second difference concerns the pattern of the positive effect in both media: in the hydroorganic mixture, a fourth-order polynomial is needed to explain the variation of \(\log K\) with \(\alpha\), whereas a second-order polynomial is enough to explain the same data in water, as shown in Table 4. A much steeper effect for low \(\alpha\) values is detected in water–dioxane because of the easier formation of the interstrand hydrogen bond N–H\(^+\)...N due to the weaker competition of the solvent molecules in the development of these interactions in a hydroorganic mixture less polar than water. As the protonation degree increases, this tendency is inverted and the polyelectrolyte effect in water–dioxane becomes less and less pronounced, being close to a plateau for \(\alpha\) values next to 0.3. The smoothing in the evolution of the polyelectrolyte effect comes from the gradual balance between the favorable tendency to form the hydrogen bond N–H\(^+\)...N and the destabilizing influence associated with the increase of charge density in the macromolecular structure.

CHEMOMETRICS

Electroanalytical Methods: Introduction

Henry S. White
University of Utah, Salt Lake City, USA

Richard M. Crooks
Texas A&M University, College Station, USA

This section focuses on recent advances in the theory, instrumentation, and methods of electroanalytical chemistry. Electroanalytical methods are well-suited for analysis of a wide range of chemical systems and problems of both fundamental and technological interest. These methods tend to have excellent sensitivity, are versatile and relatively inexpensive, and in a growing number of recent examples, exhibit the high spatial resolution required for modern analysis in the arenas of biological chemistry and nanotechnology. For these reasons, electroanalysis remains at the forefront of modern analytical methods. Advances in sensitivity and range of electroanalytical methods during the past decade, including single-molecule and single-reaction event detection, high-speed electrochemical measurements for investigations of fast kinetics, and the growing role of electrochemistry in bioanalysis have had an especially high impact on the field.

The authors contributing to this section have produced a well-rounded perspective of electroanalytical chemistry at the turn of the century. For example, the importance of electroanalytical chemistry to the field of biology and biological chemistry is represented in the article by Ewing, Neurotransmitters, Electrochemical Detection. Here, the focus of the methods is on very high spatial resolution and time-resolved detection of biological signaling events.

The theme of detection and chemical sensing is continued in the chapters by Bard, Peters, and Young. Bard pioneered the field of electrogenerated chemiluminescence, and over the years he has played a major role in elucidating the theory and developing new analytical applications of this technique. The article Chemiluminescence, Electrogenerated focuses on analytical applications, and readers interested in the use of this high-sensitivity, zero-background method for bioassays are especially fortunate to have this review at their disposal. Peters has been working in the field of electroanalytical chemistry for many years, and in Selective Electrode Coatings for Electroanalysis he discusses recent advances and applications of electrochemistry to detection. As the title suggests, the focus of this chapter is on the use of electrodes that have been engineered to respond selectively to target analytes.

This theme is continued in Ion-selective Electrodes: Fundamentals by Young. The remarkable attributes of electrodes modified with well-defined organic monolayers, and especially their application to electroanalytical chemistry, are described by Finklea in Self-assembled Monolayers on Electrodes. Such materials are useful for fundamental studies of electrode processes, but also for designing chemical detection systems. Similarly to other analytical methods, the usefulness of electroanalytical methods are greatly enhanced when they are coupled to instrumental techniques. The articles Ion-selective Electrodes: Fundamentals and Ultraviolet/Visible Spectroelectrochemistry by Anderson and Scherson, respectively, provide excellent examples of how optical methods can be coupled with electroanalytical chemistry to learn more about the system under study than either technique could provide independently. Similarly, in Microbalance, Electrochemical Quartz Crystal Ward clearly demonstrates that gravimetric methods are extremely powerful for studying both electroactive films sorbed to electrode surfaces and physical properties of electrolyte solutions. In addition to spectroscopic and gravimetric methods, scanning probe microscopies can provide detailed information about the structure and electronic properties of electrode surfaces. The article by Itaya, Self-assembled Monolayers on Electodes, deals with this subject and shows that the structure of solid electrodes, as well as the molecular structure of adsorbed organic monolayers, can be elucidated as a function of electrode potential. Finally, the article by Herrero, X-ray Methods for the Study of Electrode Interaction, describes how powerful diffraction methods can be applied in situ for the study of electrode processes.

In-situ methods are, of course, most desirable for studying electrode processes, but often it is either impractical or impossible to use such technique. So it is with ultrahigh vacuum surface spectroscopy. However, in the article Surface Analysis for Electrochemistry: Ultrahigh Vacuum Techniques Soriaga shows how well-defined electrodes, combined with carefully developed emersion procedures, provide detailed chemical and structural information about electrode surfaces.

The study of organic reaction mechanisms at electrode surfaces has been a central focus of electroanalytical chemistry for many years. In the article Organic Electrochemical Mechanisms, Andrieux provides an excellent update of the field. Of course not all electrochemical reactions occur at solid electrodes, and in recent years there has been much interest in electron transfer at liquid–liquid interfaces, for among other reasons the key role played by such interfaces in catalytic and biological reactions. This subject is covered in the...
article **Liquid/Liquid Interfaces, Electrochemistry at** by Girault.
Carter provides an excellent review on the many techniques that comprise the more traditional workhorse family of methods that fall under the category of Pulse Voltammetry. Much faster methods, based on the application of ultramicroelectrodes, are described by Forster in the article **Ultrafast Electrochemical Techniques**. These techniques offer great promise in improving the temporal aspects of electroanalytical methods in the coming years.
Taken together, this section of the *Encyclopedia of Analytical Chemistry* provides the reader with an insightful overview of modern electroanalytical chemistry and its application to real-world problems. The remarkable improvements in the sensitivity, spatial resolution, and speed of these methods is sure to expand the scope of their use in the years ahead.

**1 Introduction**

Electrogenerated chemiluminescence (ECL) is the process in which electrogenerated species undergo electron transfer reactions to form excited states that emit light. Many molecules have the potential to produce ECL, however Ru(bpy)$_3^{2+}$ (bpy = 2,2'-bipyridine) is the most common emitter used for analytical applications. Application of a voltage to an electrode in the presence of an emitter induces light production and allows for the detection of the emitter at very low concentrations. Advantages over other analytical methods include low backgrounds, precise spatial and temporal control over the emission, and the possibility of signal amplification. Commercial systems exist that use ECL to detect numerous clinically relevant analytes with high sensitivity using a variety of assay formats.

**2 Principles and Theory**

2.1 Annihilation Electrogenerated Chemiluminescence  
The ECL annihilation mechanism describes a process wherein a compound is electrochemically reduced and oxidized at an electrode (Equations 1 and 2, where $E_{R,R}$ and $E_{O,O}$ are reduction and oxidation potentials, respectively). The resulting products can react (Equation 3) to produce excited species ($^3R^*$ in Equation 3) capable of emitting light.

\[
R + e^{-} \rightarrow R^+ \quad \text{(1)}  
\]

\[
R - e^{-} \rightarrow R^+ \quad \text{(2)}  
\]

\[
R^+ + R^- \rightarrow ^3R^* + R \quad \text{(3)}  
\]

**References**

Encyclopedia of Analytical Chemistry  
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd
If the enthalpy, \( \Delta H^0 \), of the electron transfer reaction shown in Equation (3) is larger than the energy required to produce the excited singlet state from the ground state, \( E_S \) (Equation 4), then one of the products of the reaction is produced with excess energy (\( 1R^* \)). This excess energy can be emitted as light (Equation 5). This process is known as the “S-route”, indicating that the luminescence is emitted by a species in an excited singlet state.

\[
\Delta H^0 = \Delta G^0 + T \Delta S^0 = E_{R^+R}^0 - E_{R^+R^-}^0 - 0.1 \text{ eV} > E_S
\]

\[
1R^* \rightarrow R + h\nu
\]

It is also possible to use two different precursors, A and D, in an ECL annihilation process (Equations 6–8):

\[
A + e \rightarrow A^-
\]

\[
D - e \rightarrow D^+
\]

\[
D^+ + A^- \rightarrow 1A^+ + D \quad \text{or} \quad 1D^+ + A
\]

Light may be emitted from either of the possible high-energy products \( 1A^* \) or \( 1D^* \).

Even if the energetic condition of Equation (4) is not satisfied, it is possible for light emission to occur via the formation of lower energy triplet states, followed by triplet–triplet annihilation (the T-route, Equations 9 and 10):

\[
D^+ + A^- \rightarrow 3A^* + D
\]

\[
3A^* + 3A^* \rightarrow 1A^+ + A
\]

Direct emission from the triplet state is usually not observed for organic species, because they have long radiative lifetimes and are quenched before emitting. Quenching of the triplets by the radical ions or other species in the system leads to lower emission yields for the T-route than the S-route systems.

The ECL mechanisms shown above generate oxidized and reduced species at a single electrode. It is also possible to obtain emission through the steady generation of the two reactants at two different electrodes that are sufficiently close to allow the reactants to interdiffuse and react.

### 2.2 Coreactant Electrogenerated Chemiluminescence

Although analytical ECL is possible with annihilation systems,\(^{100}\) most systems require impractical procedures like the use of aprotic solvents and rigorous deaeration of solvents. Annihilation ECL is generally not convenient in aqueous solutions, because the stability range for water oxidation and reduction is too small to generate both species needed for the radical ion annihilation reaction. Moreover, one or both of the precursors are usually unstable in water. It is possible, however, to obtain ECL in aqueous solution through the use of a coreactant.\(^{101,11}\)

ECL coreactants are species that, upon electrochemical oxidation or reduction, produce species that react with other compounds to produce excited species capable of emitting light. Oxalate, \( C_2O_4^{2-} \), the first ECL coreactant discovered, represents a typical oxidative coreactant.\(^{103}\) Consider an ECL system composed of species D and oxalate in an aqueous solution. An oxidizing potential at an electrode oxidizes D to produce the radical cation \( D^+ \). It also oxidizes the oxalate, which decomposes to produce the reducing agent \( CO_2^{*-} \) as shown in Equations (11) and (12):

\[
C_2O_4^{2-} - e \rightarrow C_2O_4^- \rightarrow CO_2^{*-} + CO_2
\]

\[
D^+ + CO_2^{*-} \rightarrow D^* + CO_2
\]

In ECL systems that use coreactants, the electrode typically only oxidizes or reduces the reagents; chemical transformations of the electrochemical oxidation or reduction products provide the other required species. For example, in the oxalate system the electrode only oxidizes oxalate and the ECL reactant D; the reductant, \( CO_2^{*-} \), is generated via Equation (11). This strategy is used in most analytical applications, with the reactant D being \( \text{Ru(bpy)}_3^{2+} \) (oxidized to \( \text{Ru(bpy)}_3^{3+} \)).

A variety of different coreactants, most notably aliphatic amines, can be used with the \( \text{Ru(bpy)}_3^{2+} \) system\(^{6,12,13}\) and form the basis of many analytical schemes described in the following section. Commercial applications typically use \( \text{Ru(bpy)}_3^{2+} \) as the emitter and tripropylamine (TPA) as a coreactant. In this ECL system, developed by IGEN International Inc.\(^{114}\) in the 1980s, \( \text{Ru(bpy)}_3^{2+} \) is excited repeatedly and emits a photon many times (Figure 1).\(^{113}\) This process – often referred to as an “amplification” process – allows a single label to generate many photons and contributes to the remarkable sensitivity of ECL systems.

Other systems use coreactants that are reduced to generate reactive species. For example, ECL emission
Here, reduction of a mixture of Ru(bipy)$_3^{2+}$ and peroxydisulfate (S$_2$O$_8^{2-}$) occurs on reduction of a mixture of Ru(bipy)$_3^{2+}$ and peroxydisulfate (S$_2$O$_8^{2-}$) via the sequence shown in Equations (13–15):

\[
\text{Ru(bpy)}_3^{2+} + e^{-} \rightarrow \text{Ru(bpy)}_3^{+} \tag{13}
\]

\[
\text{S}_2\text{O}_8^{2-} + e^{-} \rightarrow \text{SO}_4^{2-} + \text{SO}_4^{2-} \tag{14}
\]

\[
\text{Ru(bpy)}_3^{+} + \text{SO}_4^{2-} \rightarrow \text{Ru(bpy)}_3^{2+} + \text{SO}_4^{2-} \tag{15}
\]

Here, reduction of S$_2$O$_8^{2-}$ generates the oxidant, SO$_4^{2-}$, which reacts with the ECL label to form the excited state of the label.

### 3 INSTRUMENTATION

The design of an instrument based on ECL depends on the intended application and the mechanism used for light generation. Three major components are found in most devices: an electrochemical cell, a potentiostat, and a light detection system. Here we discuss these basic elements and other important aspects of ECL; examples of integrated instruments are presented in later sections.

The electrochemical cell is the center of the ECL process. A basic description of electrochemical cells can be found in any introductory electrochemistry text; Figure 2 shows a diagram of a typical electrochemical flow cell used for ECL. Generation of ECL takes place in the reaction chamber, which holds a solution containing the reagents required for ECL. A reference electrode controls the electrical potential of the working electrode and thus the reactions that occur there. The reference electrode is often separated from the reaction chamber by a porous frit that prevents fluid flow between the chamber and the reference electrode compartment. A potentiostat controls and applies potentials in this three-electrode system. Computer controlled potentiostats are readily available that have the flexibility to deliver any waveform required. Solutions within the electrochemical cell must contain an electrolyte to support the passage of current. This requirement may be met in aqueous systems simply by the presence of a buffer, while quaternary ammonium salts are common electrolytes for nonaqueous solvents.

Electrodes used in electrochemical ECL cells are typically made of gold or platinum. Even these robust electrodes may require periodic cleaning, and many cells are designed for easy dismantling to aid in electrode replacement or mechanical polishing. Highly reproducible methods of cleaning the electrodes without removing them from the cell have also been introduced, for example by electrochemical oxidation of water at the electrode surface in basic media.

Light generated by ECL is typically detected with a photodetector such as a photomultiplier tube (PMT), a photodiode, or a charge-coupled device (CCD). The choice of detectors depends on several factors including size, cost, sensitivity, power requirements and the ability to image. The spectral sensitivity of the detector may also be important because different ECL emitters can have very different emission wavelengths. For example, Ru(bpy)$_3^{2+}$ emits red light at 610 nm, Os(bpy)$_3^{2+}$ emits infrared light (720 nm), while diphenylanthracene’s emission is blue (420 nm).

Efficient light detection helps to maximize the sensitivity of ECL measurements. Part of the electrochemical cell is transparent so that the light generated at the electrode(s) can escape, and the detector is positioned to maximize collection of light from the electrochemical cell. The cell and photodetector are housed in a light-tight box to reduce background light.

Virtually all integrated systems that use ECL for diagnostic measurements use the ORIGEN™ technology developed and patented by IGEN International, Inc. The essential component of the ORIGEN™ system is the measurement module, which consists of a flow cell containing an electrode and a light detection means such as a PMT or a photodiode. The current design of the ORIGEN™ measurement module includes a reusable platinum or gold electrode to generate ECL. ORIGEN™ assays typically employ magnetic microparticles as a binding phase; these microparticles are concentrated at the surface of the electrode to improve the efficiency and selectivity of the ECL process. More detailed descriptions of certain aspects of the ORIGEN™ technology are described in subsequent sections.

4 ANALYTICAL APPLICATIONS

For convenience, we divide analytical measurements that use ECL into two broad categories: assays for ECL coreactants; and assays for species capable of ECL (emitters). In the first category, biologically or pharmacologically important compounds act as ECL coreactants and react with ECL labels to generate luminescent species. The intensity of ECL measured in the presence of these coreactants is a function of the concentration of the coreactant as well as that of the emitter. ECL measurements in the presence of high, predetermined concentrations of ECL emitters can be used, therefore, as a means to assay for compounds that act as coreactants. The second category of analytical measurements uses ECL emitters as labels in affinity binding assays that attach the ECL emitter to the analyte of interest. The coreactant, typically TPA, is present in high concentrations; the amount of luminescence is thus dependent on the amount of the ECL emitter present in the assay. Since the emitters are bound to the analyte of interest, the amount of luminescence can be correlated with the concentration of the analyte.

4.1 Assays for Electrogenerated Chemiluminescence Coreactants

ECL from Ru(bpy)$_3^{2+}$ has been used to measure the concentration of coreactants such as peroxydisulfate, oxalate, and a variety of amines.$^6$ ECL assays for amines find many applications because amine groups are prevalent in biologically and pharmacologically important compounds and because amines absorb weakly in the ultraviolet/visible spectrum. ECL assays have been reported for numerous amine-containing compounds including alkylamines, antibotics, antihistamines, opiates, nicotinamide adenine dinucleotide (reduced form) (NADH) and $\beta$-blockers.$^6,16$ As a general rule, the ECL signal from alkylamine coreactants follows the order: $3^+ > 2^+ > 1^+$.\(^{13}\)

In a typical solution-based assay, a sample is combined with a solution containing Ru(bpy)$_3^{2+}$; the resulting solution is mixed and introduced into the electrochemical cell (see Figure 2). An oxidizing potential is applied to the working electrode and the ECL generated at the working electrode is measured using a light detector coupled to the flow cell. Similar methods have been used as detectors for the chromatographic separation of amines and in high-performance liquid chromatography (HPLC) systems that separate and detect amino acids for amino acid analysis.$^{17}$ Alternatively, Ru(bpy)$_3^{2+}$ may be immobilized in a thin polymer film deposited directly on the working electrode, which eliminates the need for a constant stream of Ru(bpy)$_3^{2+}$.\(^{18}\)

ECL has been used to monitor enzymatic reactions by coupling the enzymatic reaction to the generation or consumption of an ECL coreactant. The coenzyme NADH contains an amine moiety and acts as a coreactant for Ru(bpy)$_3^{2+}$, however its oxidized form (NAD$^+$) is not a coreactant.$^{18}$ Scheme 1 illustrates an ECL measurement used to assay for glucose.$^{19}$ Numerous NADH-dependent enzymes are known, allowing for the adaptation of this technique to assay for a variety of different analytes.

ECL has also been used to detect $\beta$-lactamase activity.$^{20}$ Penicillin does not act as a coreactant with Ru(bpy)$_3^{2+}$ to produce ECL but $\beta$-lactamase catalyzed hydrolysis of penicillin forms a molecule with a secondary amine that can act as a coreactant (Scheme 2). The efficiency of the ECL process can be increased by direct covalent attachment of the $\beta$-lactamase substrate to a Ru(bpy)$_3^{2+}$ derivative.$^{21}$

The ECL detection of enzyme activity has also been used to develop highly sensitive assays in which an enzyme that generates or consumes an ECL coreactant is used as the detectable label on an antibody. The presence of the antibody is determined by measuring the activity of the enzyme label via ECL.

4.2 Assays for Electrogenerated Chemiluminescence Emitters

The most common analytical uses of ECL employ the emitter as a label in affinity binding assays.$^5$

\[
\text{Glucose} + \text{ATP} \xrightarrow{\text{Hexokinase}} \text{Glucose-6-phosphate} + \text{ADP}
\]

\[
\text{Glucose-6-phosphate} + \text{NH}_2 \xrightarrow{\text{G-6-P dehydrogenase}} \text{6-Phosphogluconate} + \text{H}^+ + \text{(NADH)}
\]

\[
\text{NADH} + \text{Ru(bpy)}_3^{2+} \xrightarrow{\text{Oxidizing electrode}} \text{ECL}
\]

**Scheme 1** Schematic of reactions used to measure glucose by ECL. NADH, which is produced enzymatically, is used as a coreactant for Ru(bpy)$_3^{2+}$ ECL.
Affinity binding assays detect an analyte of interest by monitoring the binding of the analyte to one or more binding partners specific for the analyte. The label is physically linked to one of the binding partners in the assay and provides the means for detecting the coupling of the binding partner to the analyte. Several classes of binding partners are used in these assays: antibody/antigen, enzyme/inhibitor, carbohydrate/lectin, and nucleic acid/complementary nucleic acid are the most common.\(^{(22)}\)

The “sandwich assay” format (Figure 3) is often used for affinity binding assays. In a sandwich immunoassay, a sample is combined with two antibodies specific for different regions of the analyte: one of these antibodies is immobilized on a solid phase support and the other is linked to a detectable label. The presence of analyte leads to the formation of “sandwich” complexes that link the detectable label to the solid phase; the concentration of the label on the solid phase is directly proportional to the concentration of analyte. In the ECL version of the sandwich assay, the number of ECL labels on the solid phase are determined through an ECL measurement.

ECL-based affinity assays typically employ coreactants for compatibility with the aqueous conditions used in biological assays. The concentrations of the coreactants are kept constant and high to maximize the sensitivity of the detection and to prevent fluctuations in the concentration of the coreactant from changing the ECL.

Commercial instruments that use ECL and affinity binding assays utilize Ru(bpy)$_3^{2+}$ as the emitter and TPA as coreactant. The coreactant TPA dissolves in buffers, does not interfere with binding reactions, and is very stable, Ru(bpy)$_3^{2+}$ is also very stable, and is a versatile label that can be readily linked to biological molecules using various linking groups, for example, activated N-hydroxysuccinimide esters.

Magnetic microparticles are used in most commercial ECL assays as supports for affinity binding assays. In a sandwich assay format, the microparticles are coated with an antibody specific for the analyte to be measured and mixed with a solution that contains both the sample and a second antibody that is linked to one or more ECL labels. Analytes present in the sample bind to the antibodies on the microparticles, and the labeled antibody binds to these analytes to complete the sandwich complex. After the binding reactions are complete, the magnetic microparticles, (and the associated sandwich complexes) are collected on the working electrode by positioning a magnet beneath the working electrode (Figure 4). The electrode is then used to initiate ECL and the intensity of the emitted light is measured. This intensity can be correlated to the amount of emitter, and hence analyte, that is bound to the magnetic beads, which in turn can be correlated with the amount of analyte that was present in the sample. The use of magnetic microparticles enables very sensitive assay measurements by concentrating analyte and labels bound to the particles on the electrode.
Figure 4 Schematic of process used for ECL assays employing magnetic microparticles. The microparticles are captured by positioning a magnet underneath the working electrode, and the ECL is initiated upon introduction of a coreactant solution. Once the electrode is electrochemically cleaned, another sample can be introduced.

Figure 5 The ORIGEN™ analyzer (IGEN International, Inc.) was the first commercial ECL instrument (a). The ELECSYS™ 2010 (Roche Diagnostics) was designed for use in centralized testing and reference laboratories (b).

The first commercial instrument that used ECL was the ORIGEN™ analyzer (IGEN International, Inc., Figure 5). This ECL analyzer provides highly sensitive and precise assays in an automated format. Typically, the assays use magnetic microparticles as a solid support and Ru(bpy)₃²⁺/TPA as the label and coreactant, respectively. A personal computer controls the instrument and aids in the processing and storage of data. The sample and assay reagents are combined in plastic tubes; these tubes are placed in a carousel (located on the ORIGEN™ analyzer) that can accommodate 50 tubes at one time. The carousel agitates the tubes to mix the sample and reagents and to enhance the speed of the assay binding reactions. After the reactions are complete, the contents of the tubes are combined with other assay reagents and transported into the electrochemical cell. ECL is induced, the light is measured with a PMT, the contents of the cell are removed and the cell is reconditioned for the next measurement. A typical read cycle requires approximately 1 min. The ORIGEN™ analyzer is capable of conducting a broad menu of assays; different assays require only different assay reagents and, occasionally, modest modification of the instrumental procedures.

Roche Diagnostics, a licensee of IGEN International, Inc.’s technology, developed the ELECSYS™ instrument for conducting immunoassays in centralized hospital and reference laboratories. This highly automated instrument offers some of the most sensitive and precise assays available to the medical diagnostics market. (For example, the lower detection limit for the total concentration of the tumor marker prostate specific antigen (PSA) is less than 0.01 ng ml⁻¹.) Its fundamental technology and operation is similar, in principle, to the ORIGEN™ analyzer. The ELECSYS™ offers a menu of more than 40 assays, including assays for tumor markers, cardiac markers, and analytes relevant to infectious diseases, fertility therapies, thyroid disease, and many other clinical conditions. The instrument can operate in random access mode and has the capability to process STAT samples.

ECL has also been used to detect cryptosporidium in water, Escherichia coli in foods, and in the very precise quantitation of polymerase chain reaction (PCR) products for DNA-based diagnostic testing. All
these detection schemes rely on affinity binding mechanisms, and typically use Ru(bpy)$_3^{2+}$/TPA as the ECL reagents.

Recently, IGEN International, Inc. developed a new generation of ECL-based instruments. These instruments are based on IGEN’s ECL module, a self-contained, fully functional diagnostic operating system that approximates 1/20th the size of the first generation of ORIGEN™ operating systems and which has accuracy and sensitivity equal to the first generation. The ECL module forms the foundation for a wide variety of diagnostic instruments and allows for flexible design and development of ECL-based instrumentation. ECL module-based systems (Figure 6) should have a variety of applications in patient point-of-care, high-throughput drug screening, food, water and animal health testing.

5 FUTURE CONSIDERATIONS

ECL will continue as an important area of exploration for basic research. It provides a rich platform for understanding fundamental questions in chemistry, biology and physics. Applications for ECL will also continue to expand in scope and importance. Analytical and diagnostic technology based on ECL currently provides a route to simple, low-cost, highly sensitive and very precise measurements. New ECL-based systems will provide sensitive measurements in local doctor’s offices, small clinics, emergency rooms, and even in the home. These new developments will expand the impact of ECL in medicine, drug discovery, analytical science, environmental testing and industrial diagnostics.

REFERENCES

The combination of infrared (IR) spectroscopy and electrochemistry in a single measurement has been an area of active research interest since the late 1960s. IR spectroelectrochemical experiments provide insight about interfacial electrochemical phenomena and/or oxidation–reduction reaction mechanisms that cannot be obtained using either technique individually. The power of the measurement is in the complementary nature of the spectroscopic and electrochemical information available when obtained simultaneously. The combination of measurements, however, requires compromise between the IR spectroscopy and the electrochemistry because of their different sampling requirements. The need for compromise illustrates the unique strengths and weaknesses of the combined spectroelectrochemical measurement. Three spectral sampling methods are commonly used: transmission, internal reflection, and specular reflection sampling of the electrochemical experiment. Additional experimental perturbations, such as polarization and electrode potential modulation, are frequently applied to increase the spectral sensitivity toward changes confined to the electrode interfacial region. This article presents the instrumental requirements for, and a theoretical background of, different types of IR spectroelectrochemical measurements.

1 INTRODUCTION

The combination of two or more unique measurements conducted simultaneously provides an opportunity to more completely characterize a chemical system without dramatically increasing the time of analysis. This concept has driven many instrumental developments in analytical chemistry over the last 30 years, and is a principal force behind the explosive growth of the field of spectroelectrochemistry. The combination of molecular structural/electronic information that is provided by spectroscopy with the analytical sensitivity and ability to control interfacial properties afforded by electrochemistry suggests the utility of spectroelectrochemical measurements. When combining these measurements, however, care must be taken to ensure that the efforts to conduct the simultaneous determinations do not dramatically compromise the quality of either the spectroscopic or the electrochemical data. This issue is particularly important to the field of IR spectroelectrochemistry because of the strict experimental requirements of both the IR and electrochemical measurements.

The article comprises four sections. Initially, background information about the field of spectroelectrochemistry is presented. This discussion provides a perspective on the issues of spectral sampling of the electrochemical experiment, and on the instrumental challenges faced by combined IR spectroscopy and electrochemical experiments. The focus then is on the three principal sampling methods commonly used in spectroelectrochemistry: transmission, internal reflection, and specular reflection. Here, discussion centers on the experimental requirements for acquiring spectral data during the course of an electrochemical experiment.

1.1 Historical Background

The field of spectroelectrochemistry has its origins in the mid-1960s. The first publication that demonstrated the feasibility of combined spectroscopy and electrochemistry involved the spectral monitoring of the oxidation of o-toluidine using an optically transparent...
In 1966, Mark and Pons published the first application of spectroelectrochemistry to the IR region of the electromagnetic spectrum. The experimental set-up for this measurement made use of a semiconducting Ge plate as both the working electrode and as an IRE for the IR spectroscopy. As with the UV/VIS measurements by Hansen, this IR spectroscopic measurement isolated the interfacial region by using the evanescent wave emanating from the semiconducting working electrode as the incident radiation. Minimizing the spectral sampling of the bulk solvent was a driving force to the internal reflection method. Unlike in the visible region of the spectrum, typical solvents used in electrochemistry experiments are strong absorbers of IR radiation and can easily dominate the IR spectrum. In the internal reflection experiment, the evanescent wave extends approximately one-tenth of a wavelength into the solution, effectively minimizing the amount of solvent that is probed by the IR radiation. As was the case in the application by Hansen et al., use of a semiconducting working electrode compromised the electrochemical response in favor of IR transparency. Despite the poor signal-to-noise, this result clearly demonstrated the possibility of extending spectroelectrochemical measurements to the IR region of the spectrum.

In 1968 Heineman, Burnett, and Murray designed an OTTLE cell for use in the IR region of the spectrum. This cell used an Au-mesh minigrid electrode sandwiched between two IR transparent NaCl plates. This design parallels earlier OTTLE cells developed for use in the UV/VIS regions of the spectrum. As with the research by Mark and Pons, the OTTLE cell designed by Heineman et al. compromised the electrochemistry by increased resistance of the thin layer in order to accommodate the IR spectroscopic measurement. Of particular importance, both experimental configurations by Mark and by Heineman had low signal-to-noise, limiting the utility of these early IR spectroelectrochemistry measurements.

These initial demonstrations of IR spectroelectrochemistry illustrate the principal issues faced when conducting this combined measurement: (a) low spectral signal-to-noise for solutes, and (b) absorption by the background electrolyte. Several other papers appeared in the late 1960s and early 1970s that tried to address the experimental limitations with qualified success. The potential of IR spectroelectrochemistry to obtain structural information about changes that accompany electrode reactions was intriguing and provided sufficient reason for the area to be revisited as instrumentation improved over the years.

### 1.1.1 Infrared Spectroelectrochemistry

In 1966, Mark and Pons published the first application of spectroelectrochemistry to the IR region of the semiconducting SnO$_2$ electrode (CGE). Use of the semiconducting SnO$_2$ compromised the electrochemistry slightly, but the transparency of the CGE to UV/VIS (ultraviolet/visible) radiation was crucial so that the incident visible radiation could pass through the working electrode and probe the electrolyte solution during the heterogeneous redox reaction. Although the spectral monitoring in this application was with visible radiation, this demonstration of spectroelectrochemical measurements illustrated the potential utility of combining electrochemistry with spectroscopic monitoring. This measurement also illustrated that instrumental compromises, such as the introduction of resistance by the use of the semiconducting electrode, are frequently required when combining these measurements.

Several other publications in which the method of spectral sampling of the electrogenerated/consumed material was altered followed this initial publication. Hansen et al. demonstrated the ability of the SnO$_2$-coated glass to serve as the electrode as well as an internal reflection element (IRE)/waveguide in a spectroelectrochemical measurement. Here, due to the limited penetration depth of the evanescent field, they were able to restrict spectral monitoring to the region of solution adjacent to the electrode, effectively eliminating spectral response from the bulk of the solution. Murray et al. developed the optically transparent thin-layer electrode (OTTLE) by sandwiching a conducting grid, prepared from fine-mesh Au wires, between two optically flat glass or quartz microscope slides. Unlike the transmission experiment by Kuwana et al., the thin-layer cell restricted the amount of solution monitored by the spectroscopy.

Although these initial efforts in the field of spectroelectrochemistry utilized the visible region of the spectrum, they address many of the fundamental issues central to all spectroelectrochemical measurements. The initial CGE configuration used by Kuwana indicated the need to compromise the requirements of the electrochemical measurement so that spectroscopy could be conducted simultaneously. The internal reflection measurements by Hansen addressed the issue of spectral selectivity for the electrode interfacial region. The OTTLE cell design by Murray considered minimizing the interference from a complex sample by eliminating most absorbances from species in the bulk solution that are not influenced by the applied potential. These issues, which are pivotal to the development of spectroelectrochemistry in general, are particularly important as the technique migrated to the IR region of the spectrum.

### 1.1.2 Instrumental Developments of Importance to Infrared Spectroelectrochemistry

Two developments, independent of electrochemical measurements, in the mid-1960s and early 1970s made
significant contributions to the field of IR spectroelectrochemistry. In 1966, Greenler published the first of two papers that describe the IR spectroscopy of molecules adsorbed to metallic substrates using a specular reflection geometry.\(^{9}\) Greenler showed that the absorbance of a thin film was nearly 5000 times greater at a glancing angle for IR light polarized parallel to the plane of reflection compared to the absorbance obtained with light reflecting from the surface with normal incidence. Further, he calculated that the absorbance from the glancing angle reflection experiment was 25 times larger than the absorbance for a transmission experiment with a free-standing film of similar dimensions. This result provided the theoretical basis for the infrared reflection–absorption spectroscopy (IRRAS) experiment that has become a routine measurement today. As was the case with the early efforts in the field of IR spectroelectrochemistry, the external reflection measurements of supported thin films showed promise but were ultimately limited by the poor spectral signal-to-noise obtainable at the time.\(^{10}\)

Throughout the 1960s and early 1970s, instruments for IR spectroscopy were traditional spectrometers which based wavelength selection on prism or grating dispersion and slits. These instruments suffered from low source throughput, slit width limited resolution, grating/prism dispersion, detector sensitivity, and slow detector-response time. Each of these instrumental properties contributed to the low signal-to-noise of the initial IR spectroelectrochemistry measurements and the initial specular reflection measurements. It was not until Fourier transform infrared (FTIR) spectroscopy and the associated accessories (e.g., detectors and electronics) became widely available that the field of IR spectroelectrochemistry became instrumentally feasible.

During the 1970s and early 1980s FTIR equipment began replacing instruments based on the dispersion of light for collecting IR spectra.\(^{11}\) Instrumental advances that accompanied the development of FTIR addressed many of the signal-to-noise limitations found in the early IR spectroelectrochemistry measurements. The poor signal-to-noise of the initial spectroelectrochemical measurements may be attributed to the combination of low concentration of solutes that are being measured, and to the low intensity of the IR source that probes the sample at any given wavelength using the dispersive instrument. The issue of low signal-to-noise can be addressed by taking advantage of the high throughput of a Fourier transform instrument. Because of the design and use of an interferometer with a Fourier transform instrument, all frequencies are measured simultaneously. Compared to a dispersive instrument, therefore, the Fourier transform instrument may obtain the same resolution, but it does so in a fraction of the time. Consequently, multiple spectra may be obtained and co-added to increase the signal-to-noise in the same amount of time that it would take to monitor the wavelength region of interest with a dispersive instrument. This multiplex advantage leads to a substantial improvement in the signal-to-noise of the spectrum (the signal-to-noise increases by a factor of $\sqrt{N}$ where $N$ is the number of co-added spectra). Similarly, use of the interferometer to encode the wavelength data, as opposed to separating the light by dispersion and slits, leads to greater source throughput. The dispersion of the source radiation and selection of individual wavelengths by slits is inefficient and lowers the total source intensity directed through the sample. The Fourier transform instrument directs most of the source intensity through the sample and separates the individual frequencies by mathematical transformation of the interferometer encoded source intensity. In this manner, less of the typically weak IR source is needlessly wasted. Each of these characteristics of the FTIR improves the signal-to-noise of the IR spectroscopy, providing the opportunity to acquire spectra of more challenging, less concentrated samples typically encountered in spectroelectrochemistry experiments.

An additional development in FTIR offers new opportunities for IR spectroelectrochemistry.\(^{12-15}\) Step-scan FTIR instruments provide the same advantages as the continuous-scan instruments described previously; in addition, step-scan instruments introduce time as an accessible experimental parameter. In a step-scan instrument, the interferogram is built up point-by-point by moving the mirror of the interferometer in discrete steps. The timing of the experiment can be gated to the interferometer mirror steps, allowing acquisition of spectra as a function of time. With continuous-scan FTIR instruments, limited control of the time-frame is available through the interferometer scan speed and the overall instrumental resolution (e.g. the scan distance of the moving mirror). While individual scans of the interferometer are being co-added, the system being interrogated should be in some equilibrium condition. With the step-scan instrument, the time frame of the experiment is established by the dwell time at each step position of the interferometer. The dwell time may be set, providing an additional degree of flexibility for monitoring phenomena that occur at both short and long times. In this manner, one can easily monitor chemical systems at defined intervals after the interferometer mirror step, providing the opportunity to make measurements on dynamic systems whose processes occur over tens of microseconds. The utility of step-scan instruments for monitoring dynamic electrochemical processes is discussed later.

Although advances in FTIR instrumentation addressed some of the signal-to-noise limitations of IR spectroelectrochemistry measurements, these advances could not resolve all the fundamental issues faced when combining IR spectroscopy and electrochemical measurements:
The general incompatibility of the solvent types required for these two measurements.

The small quantity of material that must be detected during the experiment.

Most typical solvents for electrochemistry are poor solvents for IR spectroscopy (and vice versa). The polar solvents required to dissolve the supporting electrolyte generally have strong absorptions in the IR region of the spectrum such that the solvent would dominate the measured spectrum.

Two methods designed to reduce the solvent contribution to the IR spectrum have been developed:

- The use of thin solution layers to minimize the amount of solvent that the incident radiation samples.
- Modulating the interfacial properties and using phase-sensitive detection to selectively detect the interfacial region at the frequency of the modulation.

Advances in instrumentation over the years provide sufficient spectral sensitivity that IR spectroelectrochemical measurements have become common measurements despite the restrictions confronting them. In the following, the instrumental requirements for conducting IR spectroelectrochemical experiments are reviewed and discussed. The focus is on the strict conditions placed on sampling methods, and on how the experiment is used to obtain both electrochemical and spectroscopic data with good signal-to-noise. Where required, fundamental principles are addressed to illustrate why methods have certain restrictions, and why some experimental compromises must be made to accommodate the simultaneous spectroscopy and electrochemistry. The following sections are organized according to the main sampling geometries in common use today: transmission using the OTTLE cell, internal reflection, and external reflection. The discussion in each section focuses on the instrumentation requirements, the type of information available from the experiment, the limitations of the experiment, and the theory behind the measurements.

2 TRANSMISSION INFRARED SPECTROELECTROCHEMISTRY

Perhaps the most common applications of IR spectroelectrochemistry use the transmission mode for spectral sampling. In this case an OTTLE cell is used. Here the source radiation is directed through the transparent working electrode, sampling solution throughout the entire dimension of the thin layer. The relatively large surface area of the transparent minigrid electrode, combined with the small solution volume within the thin layer, allow complete electrochemical conversion of the solute. This method is therefore a convenient way to spectroscopically probe the structure and identity of products and long-lived intermediates (e.g. those with lifetimes of the order of minutes) of electrode reactions. In addition, the short path length of the thin-layer cell helps to minimize the absorbance by the background electrolyte. Despite the amount of use that the OTTLE cell finds today, the basic design has not significantly changed from that published by Heineman in 1968 (Figure 1).10

2.1 Optically Transparent Thin-layer Electrode Cell

Using the concepts first illustrated with UV/VIS thin-layer cells, the OTTLE cell for use in the IR region of the electromagnetic spectrum sandwiches an Au minigrid working electrode between two NaCl plates. A Teflon® gasket of known thickness spaces the two IR-transparent NaCl plates from each other and defines the thickness of the thin layer. A hole near the top of the front NaCl plate provides a path for solution to enter a larger-volume reservoir. The secondary and reference electrodes are placed in this larger solution reservoir to complete the electrochemical circuit.

Heineman used what is now commonly called an optically thick thin-layer design by placing multiple Au minigrids parallel to and spaced from each other with Teflon® gaskets. Although not required, the optically thick thin-layer design helps in the spectral detection of weak IR absorptions by allowing a larger quantity of solute to experience the applied electrode potential.
The closely spaced minigrid electrodes allow efficient conversion of the electroactive material within the thin layer because the distance required for material to diffuse to the nearest electrode is diminished in this arrangement.

The principal advantage of the thin-layer design is the ability to quantitatively convert material within the thin layer between oxidation states. The depletion of electroactive species in the thin-layer cell avoids most bulk mass-transport effects. This occurs because the size of the thin layer is small compared to that of the diffusion layer thickness over the time-frame of the measurement (minutes). The acquired IR spectrum is therefore not complicated by the presence of unreacted analyte, nor is the response complicated by species diffusing into or out of the spectral observation window. The electrochemical behavior of thin-layer cells has been described previously.\(^{16,17}\)

The open nature of the minigrid electrode allows IR source radiation to shine through the working electrode while maintaining electrochemical behavior that approximates a continuous conductor. Electrochemical behavior of the minigrid electrode can be understood using simple diffusion mass-transport arguments.\(^{18}\) Consider the diffusion behavior of electroactive species at an isolated wire (Figure 2a). When a potential sufficient to oxidize or reduce electroactive material is applied, the species adjacent to the electrode are converted, establishing a concentration gradient in the adjacent solution. Under the influence of this gradient, electroactive reactant diffuses toward the electrode where it will then react, whereas the product of the electrode reaction will diffuse away from the electrode surface into the bulk solution. Consequently, the thickness of this concentration gradient expands in a radial direction away from the isolated wire with time after application of the potential.

Now consider two wires of the same dimension placed a small distance from each other. After application of the same potential to both wires the concentration gradient associated with the electrode reaction at each wire will similarly expand in time (Figure 2b). Ultimately, the diffusion layers from these adjacent wires will overlap. At that point, the diffusion approximates the behavior of a single electrode, not a pair of independent electrodes.

The minigrid electrodes commonly used in OTTLE cells have many closely spaced wires arranged parallel and perpendicular to each other. By analogy to the simple two-wire model given above, shortly after application of the potential to the minigrid, the diffusion layers associated with any given portion of the minigrid will overlap with that of its nearest neighbors. Consequently, the depletion of electroactive material due to oxidation or reduction at the working electrode will rapidly approximate linear diffusion to the macroscopic dimension of the minigrid. The electrochemical response, therefore, has the appearance of a reaction occurring at a planar electrode despite the open structure of the minigrid. Under these conditions, the electrochemical behavior of the thin-layer cell can be simplified to a one-dimensional model of linear diffusion over a finite distance to an infinitely large planar electrode.\(^{18}\) Because the walls to the vessel are a finite distance from each other, depletion of the solute will extend to the dimensions of the thin layer, provided that the time-frame of the experiment is long compared to the time required for analytes to traverse the diffusion distance. Once this happens, the faradaic current due to the electrode reaction will return to the baseline level because all of the electroactive material within the thin layer has been converted into product. This thin-layer behavior has been described in detail previously.\(^{16,17}\)

### 2.2 Cell Characteristics

An advantage of thin-layer electrochemical behavior is that experimental limitations due to mass transport are eliminated. This thin-layer configuration allows quantitative conversion between reactants, long-lived intermediates, and products for spectral monitoring. From an electrochemical point of view, this allows separation of the effects due to the heterogeneous reaction from the effects due to mass transport phenomena. Spectroscopic determination, therefore, provides the opportunity to acquire information regarding the mechanism of electrode reactions that is not available from the electrochemical data alone.

Although the response and planar electrode behavior of the OTTLE cell provide for a conceptually simple experiment, the thin-layer minigrid working electrode introduces some experimental complications. In electrochemical measurements, a three-electrode electrochemical cell is generally used to maintain accurate control of the working electrode potential. Accurate potential control, however, can be compromised by the OTTLE cell design due to the nonideal electrode arrangement.

---

**Figure 2** (a) Illustration of the diffusion layer generated at an isolated wire, cross-sectional view. (b) Model of diffusion at two isolated wires illustrating that, after some period of time, the individual diffusion layers overlap.
Without accurate potential control, the experiment runs the risk of unevenly polarizing the working electrode (e.g. having an unequal potential distribution along the surface of the working electrode). Uneven working electrode polarization is generally avoided by maintaining the surface area of the secondary electrode large compared to that of the working electrode, and by the arrangement of the working, secondary, and reference electrodes. Typically, the surface area of the secondary electrode is 10–100 times larger than that of the working electrode. Similarly, the ideal arrangement of the working and secondary electrodes is opposite and parallel to each other with the reference electrode placed between these electrodes and close to the surface of the working electrode. These conditions prevent the generation of current paths that differ significantly from each other between the secondary electrode and points along the surface of the working electrode. Under these conditions an equipotential distribution exists along the surface of the working electrode.

If these conditions are not met, the working electrode may have a distribution of potentials along the surface, introducing the risk that a distribution of phenomena will occur at the working electrode. This would complicate the electrochemistry and make spectral interpretation difficult. Clearly the gold minigrid electrode has a large surface area, which requires a secondary electrode of large area so as to avoid uneven electrode polarization. Unfortunately, the thin-layer cell prevents placement of the secondary electrode in the ideal geometry. It is therefore likely that the working electrode experiences some uneven polarization.

Placement of the reference electrode in the reservoir away from the working electrode may also have some deleterious effects. Under normal bulk-solution experimental conditions, the solution resistance that exists along the current path between the working and secondary electrodes may be partially eliminated by placing the reference electrode between these two electrodes and close to the working electrode. In an OTTLE thin-layer cell, it is difficult to place the reference electrode in this arrangement. Consequently, substantial solution resistance may exist within the thin layer. In addition, the total solution resistance experienced will vary along the surface of the working electrode, depending on the distance between points along the working electrode and the secondary electrode. In the thin-layer geometry, it is impossible to avoid different distances between points along the working electrode and the secondary electrode, leading to variable levels of resistance within the thin layer. This variable solution resistance leads to uneven electrode polarization and potential gradients along the working electrode within the thin layer. Murray et al. illustrated this when they were able to visually monitor a color change migrating along the length of the working electrode in an OTTLE cell following the application of potential.

The presence of solution resistance and potential gradients principally influences the time response of the electrochemical measurement. Electrochemical experiments may be simply modeled as an equivalent circuit of resistors and capacitors. Because of the nature of the electrochemical experiments, the time response (e.g. how quickly the working electrode potential responds to the application of a new value) is an important parameter determined by values of the solution resistance and interfacial capacitance. Experiments in which the potential is rapidly altered in time need to have a fast response to accurately represent the electrochemical phenomena. With high resistance, OTTLE cells generally have a slow time response, resulting in distortion of the electrochemical data. For example, Heineman et al. obtained cyclic voltammetry data for the reduction of ninhydrin in their thick-layer OTTLE cell. In this experiment there is a clear distortion of the current–potential response when measured in the thin layer compared to the current potential behavior in the bulk solution, suggestive of substantial resistance effects within the thin layer.

However, for most applications of transmission IR spectroelectrochemistry the slow time response of the OTTLE cell is not debilitating. Commonly, the working electrode potential is set to some value suitable for quantitatively oxidizing or reducing the analyte. When the current decays to the baseline level, indicating that quantitative transformation has occurred and equilibrium established, the sample is spectroscopically probed. In this manner, IR spectra of the reactants, products, or intermediates of the electrode reaction are obtained at their equilibrium concentrations determined by the electrode potential.

### 2.3 New Cell Designs

Although the basic design of the OTTLE cell for IR spectroelectrochemistry has not appreciably changed since the initial publication of Heineman, some alterations aimed at improving the time response, and at improving the compatibility of the cell with organic solvents, have appeared. Hartl et al. prepared an OTTLE cell in which all three electrodes are placed within the solution thin layer. In this design a gold minigrid serves as the working electrode, a platinum mesh serves as the secondary electrode, and a silver wire serves as a pseudo-reference electrode (Figure 3). These three electrodes are melt sealed into a 200-μm-thick polyethylene spacer to establish the small dimension of the thin-layer cell. In this arrangement, all three electrodes sample the same small portion of the solution. Although this
substantial current–potential distortion.

Brisdon et al. suggest that mixing of the counter-electrode result in undesired homogeneous reactions occurring. Mixing of the products generated at these two electrodes can increase the slow current response, cyclic voltammetry of 0.018 M ferrocene (in CH₂Cl₂ containing 0.10 M tetra-

Permanently sealed cells therefore need to be discarded after several uses because of this residue build-up. Designs that rely on gaskets and pressure to seal the thin layer have also appeared. These designs allow disassembly of the thin layer for cleaning and subsequent re-use.

The design described by Hartl allows maintenance of anaerobic conditions over the relatively long time-frame of the spectroelectrochemical experiment. The exclusion of oxygen from the electrolyte solution is particularly important when studying reductive electrochemistry. Oxygen is easily reduced and can interfere with the desired electrode reactions under these conditions. In most electrochemical measurements, the electrolyte solution is purged with an inert gas immediately prior to conducting the electrochemical reduction. However, with the OTTLE cell the solution within the thin layer cannot be easily purged. In this case, the analyte solution is purged prior to placement within the thin layer. Maintaining anaerobic conditions within the thin layer over the long time-frame of the transmission spectroelectrochemical measurement is required to avoid oxygen interference with the desired electrode reaction. As they demonstrate, this feature is particularly important for spectroscopically identifying oxygen-sensitive reaction intermediates frequently encountered in inorganic chemistry.

The ease and overall utility of transmission spectroelectrochemical measurement makes it one of the more widely applied spectroelectrochemical measurements. Despite the many applications of this technique that have appeared in the literature, the basic sampling is largely the same as described by Heineman et al. in 1968. The method is most useful for identifying bulk phase products and reactants of oxidation–reduction reactions. The thin layer of the OTTLE cell compromises the time response of electrochemical reactions. Consequently, transmission IR spectroelectrochemical measurements are best suited for identifying solution components after the solution has reached its equilibrium composition at a given applied potential. Recognizing the limitations allows one to study redox reaction mechanisms using transmission IR spectroelectrochemistry and the OTTLE cell.

3 INTERNAL REFLECTION INFRARED SPECTROELECTROCHEMISTRY

Although IR spectroelectrochemical applications using an OTTLE cell are numerous, the restrictions placed
on electroanalytical measurement in this sampling configuration are significant. The resistance within the thin layer prevents rapid changes of the electrode potential; consequently, the observation of short-lived intermediates is virtually impossible. Mass transport into or out of the thin layer is also compromised by the geometry of the thin layer. This behavior is described as diffusionally decoupling the electrolyte which is trapped within the thin layer from the rest of the solution.\(^{(24)}\) This may result in a number of deleterious effects including electrolyte concentration gradients, pH gradients, and slow diffusional replenishment of materials within the thin layer. A configuration of the spectroelectrochemical cell for improved electrochemical response would probably have to eliminate the thin layer.

The thin solution layer was required for these spectroelectrochemical measurements to minimize the absorbance contribution by the bulk electrolyte. Mark and Pons, in the first publication in the field of IR spectroelectrochemistry, showed in 1966 that absorption by the bulk electrolyte could also be reduced by sampling the interface with the evanescent wave that develops at the interface where IR light is internally reflected.\(^{(5)}\) In this application, the evanescent wave emanates from a Ge plate configured as both the working electrode and as a waveguide for IR radiation (Figure 4). Although the spectroscopic signal-to-noise was poor, this measurement demonstrated the potential for using the evanescent wave for IR spectroelectrochemical measurements.

Hansen\(^{(25)}\) and Harrick\(^{(26)}\) demonstrated that light incident on an interface between a phase of high refractive index and a phase of lower refractive index reflects at the interface with a small portion of the incident light transmitted through the interface when the incident angle is greater than a critical value. The transmitted light, called the evanescent wave, decays exponentially into the lower-index medium with the depth of penetration being dependent on the wavelength of the incident light and on the angle of incidence. Typically, this decay length is approximated as one-tenth of the wavelength of the incident light. For IR spectroscopy, therefore, the spectral sampling by the evanescent wave will be of the order of hundreds of nanometers. The penetration of the evanescent wave is smaller than the typical diffusion layer thickness in electrochemical experiments, indicating that internal reflection spectroscopy will sample only the interfacial region during the IR spectroelectrochemical experiment. Because of the very small interfacial region probed by the internal reflection method, IR absorption by the bulk solvent is not significant and the need for a thin-layer configuration is eliminated. Eliminating the thin layer removes many of the electrochemical restrictions imposed on the experiment by the OTTLE cell (e.g. slow time response and resistance effects), and provides the opportunity to observe transient electrochemical phenomena on faster timescales.

Unfortunately, the combination of the IRE and the working electrode into a single package introduces some new compromises to the combined spectroelectrochemical experiment. Mark and Pons,\(^{(5)}\) as well as subsequent work by Tallant and Evans\(^{(7)}\) and by Reed and Yeager,\(^{(8)}\) used semiconducting $n$-doped Ge as both the working electrode and the IR-transparent IRE in

\[\text{Figure 4 IR spectroelectrochemical cell with a Ge working electrode–waveguide combination for internal reflection spectroelectrochemistry. MIR = multiple internal reflections. (Reprinted by permission from H.B. Mark, B.S. Pons, 'An In Situ Spectrophotometric Method for Observing the Infrared Spectra of Species at the Electrode Surface during Electrolysis', } \textit{Anal. Chem.}, \textbf{38}(1), 119–121, \textcopyright \text{1966} \text{American Chemical Society.} \]
their spectroelectrochemical experiments. Because of the semiconducting nature of Ge, there was significant internal resistance across the Ge plates (100–2000 Ω as measured across a 5-cm dimension by Tallant and Evans\(^7\)). Any resistance in the electrochemical measurement, whether it comes from the electrode or the solution, places restrictions on the time response of the measurement. Additional doping can decrease the resistance of the semiconducting Ge, but improvements in the electrochemical performance in this case are offset by the diminished IR transparency of the more highly doped Ge. Tallant and Evans suggested the use of metallic films deposited on the surface of the IR-transparent Ge as a way of increasing the conductivity of the working electrode.\(^7\) In this case, the evanescent wave must penetrate through the metal film to sample the electrolyte solution. When using a metallic overlayer as the working electrode, the metal layer must be sufficiently thin to allow the evanescent wave to penetrate, because IR radiation is strongly absorbed by metallic films. To function as an electrode, however, the metallic film must be sufficiently thick to ensure a good, continuous conductor. As with the OTTLE cell, the different requirements of the spectroscopy and electrochemistry elements of the combined measurement require a compromise that ultimately may degrade the performance of both portions of the measurement.

It is evident that the strengths of the IRE spectroelectrochemical experiment are complementary to those of transmission IR spectroelectrochemistry with the OTTLE cell. Although the OTTLE cell provides a convenient method for acquiring spectra of reactants, intermediates, and products in the bulk solution, measurements that use IRE sampling isolate the interface and might be useful for identifying species at the electrode interface or within the electrochemical double layer during electrode reactions.

### 3.1 Evanescent Waves

A detailed discussion of the theory of internal reflection and evanescent wave properties is found elsewhere and is not reproduced here. Hansen\(^{25,27}\) and Harrick\(^{26}\) provide details for solving the boundary value problem for transmission and reflection of electromagnetic radiation at interfaces between media of different refractive indices using Fresnel’s equations. Hansen in particular explored systems of relevance to spectroelectrochemical applications (e.g. two-layer and three-layer systems in which the middle layer is a thin metallic film).\(^{25,27}\) He shows that the evanescent wave has a field strength that decays exponentially into the electrolyte medium. For a three-layer system (Figure 5), Equations (1–3) describe the field strength of the evanescent wave:

\[
\langle E_{z}^2 \rangle = \frac{n_1 \sin \theta_1}{n_3} t_1 \exp \left( \frac{4\pi}{\lambda} \Im \xi_3 (z - h) \right)
\]

(1)

\[
\langle E_{\parallel}^2 \rangle = \frac{\xi_3}{n_3} t_1 \exp \left( \frac{4\pi}{\lambda} \Im \xi_3 (z - h) \right)
\]

(2)

\[
\langle E_{\perp}^2 \rangle = |t_\perp|^2 \exp \left( \frac{4\pi}{\lambda} \Im \xi_3 (z - h) \right)
\]

(3)

In these equations, \(\langle E_{\parallel}^2 \rangle\) and \(\langle E_{\perp}^2 \rangle\) are the mean electric field strengths in the \(z\) and \(x\) directions resulting from light polarized parallel to the plane of reflection, \(\langle E_{z}^2 \rangle\) is the mean electric field strength resulting from light polarized perpendicular to the plane of reflection, \(n_1\) and \(n_3\) are the refractive index and complex refractive index of the incident and final phases, \(h\) is the thickness of the metallic layer, \(\theta_1\) is the incident angle, \(\xi_3\) is the complex refractive index of the third phase multiplied by the cosine of the incident angle, \(t_\parallel\) and \(t_\perp\) are symbols representing Fresnel’s equations for the transmitted light polarized perpendicular and parallel to the plane of reflection, and \(\lambda\) is the wavelength of the incident light. The Im function indicates that the imaginary part of the complex refractive index is taken, and \(z\) is defined in Figure 5.

Because the imaginary portion of \(\xi_3\) is negative, the field strength decays exponentially into the lower index medium. It is estimated that the penetration depth, \(d_p\), of the evanescent wave is equal to the distance away from the interface where the amplitude of the evanescent electric field strength decays to 1/e of its initial value. This is given by\(^{28}\)

\[
d_p = \frac{\lambda}{2\pi \sin^2 \theta - (n_2/n_1)^2}
\]

Equation (4), strictly applied, is for a two-layer system; however, it is frequently used to approximate the

---

**Figure 5** Diagram of the three-layer model of the interface between an IRE, a thin metallic layer and the electrolyte solution used to define the Cartesian axes of the boundary value problem for calculating the mean electric field strength of the evanescent wave.
penetration depth of three-layer systems where the assumption is made that the metallic film is sufficiently thin so as not to dramatically attenuate the evanescent wave. This is generally thought to be the case if the thickness of the layer is much smaller than the wavelength of the incident light. Equation (4) illustrates that the sampling depth of the evanescent wave in an internal reflection experiment depends explicitly on several factors:

- the refractive indices of the incident (e.g. the waveguide with high refractive index) and final layer (e.g. the electrolyte solution);
- the angle of incidence;
- the wavelength of the incident radiation.

Equation (4) illustrates that, over a broad range of angles, the sampling depth of the internal reflection experiment can probe different total dimensions of the interface. As the angle approaches the critical angle, the penetration depth increases, as expected. This behavior suggests that internal reflection methods may be used to spectroscopically probe interfacial electrolyte concentration gradients at the electrode interface by varying the angle of the incident radiation. Equation (4) also shows that over the mid-IR region of the electromagnetic spectrum, the sampling depth changes dramatically. For example, \( d_p \) is calculated to change from 600 nm at 1000 cm\(^{-1}\) to only 200 nm at 3000 cm\(^{-1}\). This result suggests that quantitative spectroscopic analysis may be distorted if using spectral features having different wavelengths for analysis, a problem when using FTIR spectroscopy.

### 3.2 Sampling in Internal Reflection Measurements

Although not as widely applied as other IR spectroelectrochemical methods, several different sampling methods have been reported since the pioneering work of Mark and Pons.\(^5\) The following examines these different methods.

#### 3.2.1 Multiple Internal Reflections

The initial spectroelectrochemical experiments of Mark and Pons,\(^5\) Tallant and Evans,\(^7\) and Reed and Yeager\(^8\) used a multiple reflection IRE for acquiring the IR spectrum. In this arrangement, the Ge waveguide is much longer than it is thick. As a consequence, the incident light reflects multiple times within the Ge working electrode as it propagates down the length of the waveguide. At each reflection of the incident light with the interface between the Ge plate and the electrolyte solution, attenuation of the evanescent wave due to absorbance by species on the electrolyte side of the interface is possible. Consequently, the multiple reflections can lead to greater spectroscopic signal-to-noise for species at the electrode interface.

Ashley et al. demonstrate the utility of multiple internal reflection Fourier transform infrared spectroscopy (MIRFTIRS) for studying material adsorbed onto a metallic interface.\(^29\) Here they investigate the adsorption of SCN\(^-\) on silver and gold films by MIRFTIRS, and compare the results to other spectroelectrochemical experiments. Their spectroelectrochemical cell is similar in construction to Mark and Pons’; however, Ashley et al. used a 200-nm thin film of Au or Ag deposited on Si substrates as the working electrode. The sampling depth of the IR radiation in this cell was estimated by Ashley et al. to be approximately of 350 nm for 2000 cm\(^{-1}\) incident radiation. This estimate of the sampling depth apparently does not consider the attenuation of the incident radiation that may occur due to the presence of a relatively thick layer of metal between the Si IRE and the electrolyte solution. The thickness of the metal layer is approximately 5\% of the wavelength of the incident light in this experiment; consequently, estimating the evanescent wave penetration depth with the expression for a two-layer system is not adequate for this system. The 200 nm thin metal film used by Ashley et al. is approximately 10 times larger than metal thin films used in other internal reflection experiments.\(^24,30–33\) The presence of the thick metal film probably attenuates the penetration depth of the evanescent wave (considering the dependence on \( h \), i.e. the metal film thickness, in the mean evanescent field strength given by Equations 1–3). This probably makes the actual sampling depth in this application somewhat less than this estimate of \( h \). If the sampling depth is assumed to be much smaller than the initial estimate, the spectral results with the thick metal layer correlate with the observation that these measurements detect only SCN\(^-\) species adsorbed directly to the metal (e.g. those species within approximately 10 Å of the interface). In this case, the multiple internal reflections provide sufficient sampling of the interface to allow adequate signal-to-noise for observation of the adsorbed species. The evanescent wave attenuation by the thick metal film apparently prevents the observation of species in solution.

Sherson et al. also compared MIRFTIRS with other sampling techniques for IR spectroelectrochemistry.\(^34\) Unlike Ashley et al., they prepared their metal film by patterning a thin metal section (thickness estimated to be approximately 4 nm) down the middle of the IRE surrounded by a thicker metal layer on the IRE periphery (Figure 6). A problem that has been observed with very thin metal layers on IREs is the formation of nonisotropic, nonideal interfacial structures (e.g. island formation) during the deposition step.\(^30,35\) Island formation may result in electronic isolation of
portions of the thin metal layer, making electrochemical phenomena inhomogeneous across the surface of the metal. The intent of the patterned electrode was to maintain a thin metallic region for efficient evanescent wave penetration into the solution while also ensuring that the bulk metal film was sufficiently thick to maintain good conductivity for the electrochemistry. This cell demonstrates almost no electrochemical distortion due to resistance effects, and no obvious spectral irregularities from a nonisotropic surface. IR spectra with excellent signal-to-noise that are qualitatively equivalent to those obtained by IRRAS methods are obtained using this spectroelectrochemical cell.

Multiple internal reflection methods demonstrate excellent signal-to-noise characteristics. This is probably due to the many times that the interface is sampled as the incident light propagates down the waveguide. Ashley et al. showed that MIRFTIRS measurements can use thicker metallic films than others predict, probably due to the many times that the interface is sampled. Sherson demonstrated that patterned interfaces can provide continuous electrical contact across extremely thin metallic films. These results demonstrate the applicability of MIRFTIRS for studying interfacial electrochemical phenomena.

3.2.2 Single Reflection Interfaces

Single reflection interfaces have also been used as IREs for IR spectroelectrochemical measurements. A typical spectroelectrochemical cell for a single internal reflection experiment is shown in Figure 7. In these applications, the IRE is a prism rather than a thin waveguide. Many different materials have been used for the prism (e.g., Ge, GaAs, Si, KRS-5, ZnSe, CdTe, BaF2, CaF2). Depend on the optical properties of the prism material and the adjacent solution, it is found that allowable dimensions of the metallic layer for adequate penetration of the evanescent wave through the metal film vary from 10 nm up to 40 nm. This dependence of the allowable metal thickness on the optical properties of the prism is evident from Hansen’s treatment of the three-layer system (Equations 1–3), yet it introduces complications when trying to compare results that are obtained with different IRE–metal overlayer combinations.

Johnson et al. attempted to rationalize behavioral differences observed based upon the prism–metal film combinations, particularly with regard to the inability of Hansen’s treatment to make accurate quantitative predictions for some of these IRE–metal overlayer combinations. They found that the optical properties of the metal films are different from those of the bulk metals, making predictions based on bulk metal properties invalid. They proposed that the origin of these property differences comes from two effects, namely the inhomogeneous nature of the metallic thin film and the interdiffusion of semiconducting metalloids and the metal overlayer. The three-layer model used for theoretical description of the internal reflection behavior at an IRE, as originally developed by Hansen, assumes that all layers are isotropic. However, when depositing a thin metal layer for use as an electrode it is known that the metal film is not isotropic. Instead, it forms initially as isolated islands that merge into a rough, continuous film as more material is deposited. Because of the inhomogeneities in the dimensions of the metal film, the isotropic model that is generally used does not accurately describe the system.

The role of interdiffusion is clearly demonstrated when comparing spectral results obtained with thin metal films deposited on an ionic reflection element.
(such as BaF\(_2\)) and a semiconducting metal (such as Ge)\(^{30,37}\). With Ge substrates, diffusion of the Ge into the metal overlayer may occur and change the optical properties of the metal overlayer. With the ionic crystal, interdiffusion of the substrate into the metal overlayer will not occur. When measurements were made with BaF\(_2\) substrates coated with metallic thin films, close agreement between experimental results and Hansen’s theory was obtained.\(^{30,35}\) Agreement between experimental spectral data with the metal layer on a Ge substrate and theoretical predictions was not as close.

The single-reflection arrangement using a prism IRE with a thin metallic layer for IR spectral sampling is generally known as the Kretschmann arrangement, and has been widely applied for studying the structure of materials adsorbed on metallic films. Kretschmann IRE cells possess several characteristics that are potentially useful for spectroelectrochemical applications. The metallic thin film can be used as the working electrode in a spectroelectrochemical experiment, provided that it is thick enough to conduct. The film attenuates the evanescent wave penetration into the electrolyte, serving to further isolate the interface for spectral observation. As demonstrated in MIRFTIRS applications, this provides improved selectivity for adsorbed materials relative to bulk species. Finally, the extremely thin metallic films (generally 10–20 nm thick) typically used in this application are found to enhance the IR spectrum of species adjacent to the metallic layer.\(^{31,32,38}\)

The enhancement of the IR spectrum of adsorbed material when using the Kretschmann arrangement is generally known as surface-enhanced infrared absorption spectroscopy (SEIRAS), and was first demonstrated by Hartstein et al. in 1980.\(^{38}\) Like the related technique of surface-enhanced Raman spectroscopy (SERS), SEIRAS has been associated with the roughness of the thin metallic layer. However, unlike SERS, the phenomenon is observed using a variety of metallic substrates including Ag, Au, Cu, In, Pt, and Pd.\(^{30,36}\)

Osawa et al. have studied applications and the theory of the SEIRAS technique.\(^{35,36,39}\) They find that the enhancement is influenced by the optical properties of the IR-transparent substrate, the conditions used in depositing the metal film on the substrate, and the overall morphology of the film. Although each of these factors plays a role in the SEIRAS effect, the effects are not independent of each other. For example, when comparing BaF\(_2\) and Ge IRE substrates (\(n = 1.42\) and 4.0, respectively), Osawa found the SEIRAS intensity to be larger for the metal films deposited on BaF\(_2\). This result can be partially understood from the optical properties of the materials and the field strength of the evanescent wave in a three-phase system (Equations 1–3). The closer the optical properties of the waveguide and the phase on the opposite side of the metal film, the larger will be the strength of the evanescent electric field. This result corresponds with those of Johnson.\(^{37}\)

Different substrate–metal combinations generate different metal film morphologies when the film is vapor deposited. Wetting of the substrate surface during deposition refers to the ability of the deposited material to spread over the substrate surface and form an isotropic layer. The ability of a metal vapor to wet the substrate is related to the relative surface energies of the substrate and the deposition metal. In general, metal deposition initially occurs as isolated metal islands that eventually merge together as additional metal is deposited. The amount of metal required before the isolated islands merge into a continuous film depends on the efficiency with which the metal spreads across the substrate. Inefficient wetting of the substrate suggests that the metal will not deposit as a continuous film; rather, it will deposit and grow as discrete ellipsoids. These ellipsoids generate morphologies/roughness of the metal film at the interface, a property that has been identified as an important contributor to the SEIRAS effect.\(^{40,41}\) Different IRE materials have different surface energies; consequently, it is expected that there will be morphological differences between substrates resulting from the vapor deposition of thin metal films.

Osawa et al. report enhancement of the IR spectrum by a factor of 1000 when using a thin metal film made up of discontinuous islands of prolate ellipsoids.\(^{39}\) In general, the deposition of metals on substrates begins by forming individual islands at very small coverage (5 nm films and smaller), and these islands merge into a continuous film as the thickness of the layer increases. The term “thickness” for a vapor-deposited metallic film is perhaps a misnomer because it is assumed that all the evaporated metal deposits on the substrate to form a uniformly thick film. The film thickness is calculated based upon the rate of thermal evaporation of the source metal and not on the actual thickness of the deposited film. When the individual metallic islands begin to merge, the amount of spectral enhancement decreases sharply (Figure 8).\(^{40}\) This result is unfortunate for spectroelectrochemical applications because the electrochemistry needs to have a continuous metallic film to ensure uniform conductivity across the surface of the IRE. For spectroelectrochemical applications, therefore, the amount of spectral enhancement does not approach the factor of 1000 reported by Osawa et al. Tenfold sensitivity increases are observed in spectroelectrochemical applications where a continuous film is required (the sensitivity enhancement is calculated by comparison to spectra acquired by other IR methods).

Several groups have considered the mechanism of SEIRAS theoretically, with the most detailed descriptions given by Osawa et al.\(^{35,36,39,40}\) and by
respectively) produced an enhanced IR spectrum. This reflection and perpendicular to the plane of reflection, field is linearly polarized and aligned with the plane of both p- and s-polarized light (that is, light whose electric operating. At low metal thickness (approximately 5 nm), found that the thickness of the metal played a significant role in determining the type of enhancement mechanism Suetaka et al. investigated different contributions to the enhancement of the IR absorption. They found that the thickness of the metal played a significant role in determining the type of enhancement mechanism. At low metal thickness (approximately 5 nm), both p- and s-polarized light (that is, light whose electric field is linearly polarized and aligned with the plane of reflection and perpendicular to the plane of reflection, respectively) produced an enhanced IR spectrum. This absorption was attributed to an electromagnetic effect. At higher coverage (200 nm), only the p-polarized light was found to enhance the IR absorption. This observation is important to spectroelectrochemical applications because these generally use thick metal film electrodes. The p-polarized light introduces a directional aspect to the IR experiment that may be used to obtain information about the structure of the molecule adsorbed to the interface. Originally, the thick film behavior was attributed to an excitation of delocalized surface plasmons. Osawa et al. showed later that the surface plasmons could not explain the broad range of incident angles that lead to the observed enhancement. They assert that the polarization dependence of the enhancement with the thick films is likely a function of the continuous nature of the metal layer. That is, the p-polarized light can more efficiently induce polarization changes of the metal film in a direction normal to the macroscopic dimension of the film than can the s-polarized light.

For spectroelectrochemical applications, the field enhancement at the metal–particle interface has several benefits. The large magnitude of the electric field at the interface increases the absorbance by material adjacent to the metallic thin film. This leads to a spectral response that is approximately 10 times larger than that obtained by other IR spectroelectrochemical techniques. Hatta et al. showed that the SEIRAS enhancement was dependent upon the incident polarization as well as the thickness of the metallic layer. For thicker metal layers (approximately 20 nm) where the islands have merged into a continuous film, only incident light that is p-polarized generated the enhanced field at the interface. Because the metallic film is continuous in electrochemical applications, and because the incident radiation probes...
the interface by internal reflection, the field enhancement on the solution side of the interface has a principal direction largely normal to the macroscopic dimension of the IRE interface. The directional aspect of the induced electric field results in selective differentiation of the vibrational modes for molecules adsorbed on the surface. Vibrational modes whose transition dipole moment change is aligned with the enhanced field are observed, whereas those modes whose transition dipole moment change is perpendicular to the field enhancement are not observed. This behavior is generally known as the surface selection rule and provides information about the orientation that adsorbed molecules make with respect to the interface. Inspection of the equations for the evanescent wave field strength given by Hansen (Equations 1–3) shows that the evanescent wave has polarization components both perpendicular and parallel to the plane of reflection. For the internal reflection experiment, therefore, the surface selection rules must arise from the field enhancement due to the SEIRAS effect.

Taking advantage of this polarization dependence of the field enhancement, Hatta et al. demonstrated a polarization modulation method used in conjunction with the Kretschmann configuration.\(^{(43)}\) In this method, alternating p- and s-polarized light is reflected from the prism interface. The reflected light is detected and demodulated with a phase-sensitive lock-in amplifier at the frequency of the polarization modulation. Because only the p-polarized light efficiently couples into the continuous metallic film to enhance the IR spectrum of adsorbed material, modulating the incident radiation between p- and s-polarization has the effect of introducing time dependence to the spectral signal. Consequently, lock-in detection improves the signal-to-noise ratio for the IR spectrum obtained in this fashion. Because this polarization effect is present only with continuous metallic films, the polarization modulation technique can easily be applied to electrochemical systems.

The polarization modulation used with the Kretschmann arrangement illustrates a method where modulating the analytical signal improves the signal-to-noise of the experiment. In this application, the polarization modulation relies on the properties of the interface to differentiate the effects measured.

### 3.3 Dynamic Measurements

Osawa et al. recently demonstrated how SEIRAS measurements using the Kretschmann arrangement could be used to characterize dynamic (e.g. short time-frame) electrochemical phenomena.\(^{(44)}\) Typical IR spectroelectrochemical measurements yield spectra under equilibrium conditions; that is, conditions at some time after the potential alteration has occurred and the system current has returned to baseline levels. In making spectral measurements in this fashion, the dynamics of the electrode process are lost. This restriction is largely due to the incompatible time-frames of the electrochemical phenomena (milliseconds) and the IR spectral acquisition time when using FTIR (seconds to minutes).

The advent of step-scan FTIR instrumentation makes dynamic FTIR measurements possible. With this instrument, the moving mirror of the interferometer is not continuously scanned; rather, it is sequentially stepped and held at discrete positions along the scan dimension. In scanning interferometry, each scan of the moving mirror represents the acquisition of one spectrum, and the signal-to-noise of the final spectrum is improved by co-adding many individual spectra. Depending on the scan distance and the mirror velocity, acquiring one spectrum requires some defined time. In a step-scan instrument, the signal is integrated not as a function of the number of scans, but as a function of time at each step position. With this instrument, therefore, the interferogram is built up point-by-point with the signal-to-noise of the final spectrum being related to the dwell time at each mirror position. If used effectively, there is the opportunity to gate an experiment to the individual steps of the interferometer so that time-resolved spectral data might be acquired. In this manner, one may obtain IR spectra at a defined duration after application of some experimental perturbation. For example, if the interferometer mirror position step were synchronized with a change in the applied potential at the working electrode, then it would be possible to acquire IR spectra at some defined time after the potential change. Alternatively, one could use the interferometer mirror steps to initiate a linear potential scan of the working electrode. In this case, one could acquire spectra of the interface at discrete potentials (because time and potential are linearly related in a linear potential scan experiment) during the potential scan.

To conduct these synchronized experiments, the system being studied must exhibit reversible behavior with respect to the perturbation applied. This requirement is easily understood because the experiment must be repeated many times at each mirror position so that the corresponding interferogram can be built up point-by-point. Consider that each mirror position is providing only a portion of the total interferogram. Only after each portion of the interferogram (e.g. at each mirror position) is collected and assembled can the final spectrum be calculated. If the system being studied is not reversible with respect to the experimental perturbation, then the chemical system is different at each mirror position. To obtain a sensible spectrum, then the condition of the sample must be the same at every interval following the mirror position change, requiring that the associated chemistry be reversible and reproducible.
Osawa et al. have demonstrated the utility of step-scan coupled with the Kretschmann arrangement for monitoring electrochemical processes at short times.\(^{(44)}\) In this application, they monitor the deposition of heptaviologen radical cation as a function of time after the electrode is stepped from a value where no electrochemistry occurs (−0.2 V) to a value where the mass-transport-limited one-electron reduction of heptaviologen occurs (−0.55 V). After the potential step, spectral data are acquired at discrete times (every 100 µs) at each mirror position. From this spectral data, individual IR spectra of the interface corresponding to every 100 µs after the potential step are constructed (Figure 10). This provides a dynamic spectral picture of the interfacial electrochemical phenomena with time resolution acceptable for following dynamic electrode processes. The combination of step-scan FTIR and the rapid response, low resistance spectroelectrochemical cell used in the internal reflection sampling mode provide the instrumental characteristics necessary for this experiment.

### 3.4 Other Sampling Configurations

Internal reflection IR spectroelectrochemical measurements in which the working electrode is a thin metal film deposited on the IRE are shown to have excellent sensitivity for material adsorbed to the metal thin film. However, the technique is poor at monitoring species present only in the solution phase. Sherson et al. address this shortcoming by using a channel flow electrochemical cell (Figure 11).\(^{(34,45)}\) With this cell, the electrochemical process and the spectral monitoring are separated in space. Using a flowing solution through a thin channel, electroactive material undergoes an electrode reaction at the working electrode and then it is swept into the spectroscopic observation region by the flowing solution. The electrochemical response to the flowing stream follows standard steady-state electrochemical behavior, with the flowing stream maintaining the concentration of the electroactive material constant at the diffusion layer boundary.\(^{(16)}\) Because the evanescent wave penetrates only a small distance into the solution phase, only species within the diffusion layer are observed spectroscopically. The concentration determined by the spectroscopic measurement is a function of only the down stream distance from the near edge of the working electrode. This method holds great promise for extending the internal reflection sampling geometry for studying solution phase reactants and products of electrode reactions.

## 4 SPECULAR REFLECTION

The strengths and weaknesses of transmission spectroelectrochemistry with an OTTLE cell and internal reflection spectroelectrochemical measurements are somewhat complementary to each other. The OTTLE cell allows spectral observation of solution phase products and intermediates of electrode reactions. However, this method does not provide any information about material at the solution–electrode interface. Because of the shallow
depth of penetration, internal reflection methods are most sensitive to the interface and provide almost no information about material in the bulk solution. Resistance effects limit transmission measurements to static, equilibrium conditions whereas, as demonstrated by Osawa et al. with step-scan FTIR, sampling by internal reflection allows acquisition of spectra during dynamic electrochemical phenomena.

Ideally, a single IR spectroscopic sampling method would be able to provide information about both solution phase and adsorbed materials, as well as information about dynamic electrode processes. One sampling method that may be able to provide this information uses a specular, or external, reflection sampling geometry. In this geometry for spectral sampling, the IR source passes through a small thickness of the bulk solution before and after reflection, sampling the solution phase species. According to Greenler, the phase behavior of reflected light provides an enhanced sensitivity for species at the metallic surface. The specular reflection sampling method therefore appears to be able to provide information about both solution phase and surface adsorbed material.

4.1 Spectroelectrochemical Cells for Specular Reflection Experiments

Although specular reflection has the potential to provide more spectral information than either transmission or internal reflection methods, it also has limitations. Primary among these limitations is the required use of a solution thin layer. The thin layer, as in transmission experiments, is required to improve the total throughput of the source radiation through the highly absorbing solvent. As with the OTTLE cell, use of the thin layer creates resistance effects and possible uneven polarization of the working electrode interface, limiting the opportunity for dynamic measurements. Designs of the specular reflection IR spectroelectrochemical cells provide additional flexibility, compared to OTTLE cells, which help to reduce resistance effects and improve the time response of the measurements.

The cell design used by Bewick et al. in the first demonstration of specular reflection IR spectroelectrochemistry is shown in Figure 12. Here the working electrode was a Pt disk mounted on a syringe plunger. The cell body was fashioned from the syringe barrel with the front sealed with an IR-transparent window. When assembled, the working electrode is inserted through the syringe barrel until it is pressed against the IR-transparent window, forming the solution thin layer with a thickness estimated to be approximately 10–20 μm. To complete the electrochemical circuit, the secondary electrode is a Pt coil placed close to the IR-transparent window and surrounding the working electrode. The reference electrode tip is also placed close to the edge of the working electrode using a Luggin capillary. Although the electrochemistry is conducted on a thin layer of solution, in this specular reflection cell design the placement of the secondary and reference electrodes is more ideal than in the OTTLE cell, helping to reduce some of the resistance effects.

The cell design by Bewick et al. is similar to the full-edge current flow thin-layer spectroelectrochemical cell described by Lin and Kadish. Although Lin and Kadish’s cell is designed for use in the UV/VIS region of the spectrum, the placement of the secondary electrode surrounding the working electrode and just outside of the thin layer is like the design of Bewick et al’s. Similarly, placement of the reference electrode tip just outside the thin layer is similar to the cell of Bewick et al. Lin and Kadish’s thin-layer cell has excellent current–voltage response, suggestive of reduced resistance effects (compared to that of a traditional OTTLE cell). Indeed, equivalent circuit analysis suggests that the more ideal arrangement of the electrodes, particularly the reference electrode, make significant contributions toward reducing the resistance effects.

In addition to possible thin-layer solution resistance effects, a problem introduced by this design that should be addressed is the need to carefully align the IR-transparent window with the working electrode. Unlike the OTTLE cell, where the boundaries of the thin layer are held apart and parallel to each other by a Teflon® gasket of known thickness, the specular reflection cell does not define the thin-layer dimension. Consequently, the thin-layer size is difficult to reproduce experiment to experiment. Defining the thin-layer dimensions with partial gaskets at the edge of the working electrode is possible; however, this may increase the resistance of the thin layer by impeding current paths. The IR-transparent window and the surface of the electrode must also be parallel to each other.

other. If they are not parallel, then the thickness of the thin layer will vary along the surface of the working electrode. The irreproducibility of the solution thin layer may result in variation in the spectral signal-to-noise from one experiment to another.

Although the basic design principles used by Bewick et al. in constructing their specular reflection cell have not changed, many alternative designs have appeared. These designs address the sampling issues identified above.

Mosier-Boss et al. describe a cell, similar to that of Bewick et al., that is machined from a glass ceramic material. The arrangement of the working, secondary, and reference electrodes is similar to the glass cell of Bewick et al. By machining the cell body from a ceramic, higher tolerances for the electrode and window alignments are possible. These higher construction tolerances improve the reproducibility for generating the solution thin layer, for ensuring that the IR-transparent window and the working electrode are parallel to each other, and for decreasing the dimension of the thin layer. Using this cell with a 10-µm thin-layer thickness, Mosier-Boss et al. were able to obtain current versus potential responses in cyclic voltammetry experiments that are largely undistorted by resistance effects. This particular current versus potential response is characteristic of semi-infinite diffusion, not thin-layer electrochemistry. At these potential scan rates, the 10-µm dimension of the thin layer is much larger than the diffusion layer thickness. This cell can respond quickly to changing potentials (e.g. potential changes of 100 mV s⁻¹), and is not subject to high thin-layer resistance effects; consequently, it is not limited to static, equilibrium electrochemical measurements and could be used in dynamic electrochemical measurements. This result illustrates the effectiveness of using more ideal electrode placements on reducing resistance effects within the thin layer.

Reproducing the thin-layer thickness is a difficult, yet important, parameter to the specular reflection spectroelectrochemistry experiments. Frequently, one needs to collect spectral data, pull the electrode away from the window to allow replenishment of the thin layer, and then re-establish the thin layer for additional spectroscopic measurements. If the thin-layer thickness is not reproduced, spectra acquired before and after the thin-layer disruption cannot be reliably compared with each other. Several spectroelectrochemical cells have been designed in which the working electrode is mounted on a micrometer. The micrometer allows exact and reproducible placement of the working electrode surface based on the micrometer setting.

Zhang and Lin sought to reduce even further the resistance within the thin layer by using an electrode microarray as their working electrode. Here, rather than having a continuous disk, they use a 3 × 3 array of 1-mm diameter disks (Figure 13) as their working electrode. In this design, nine closely spaced, full-electrode current-flow thin-layer cells, with dimensions much smaller than that of a single disk electrode with an equivalent surface area act as a single working electrode. Using equivalent circuit analysis, they show that the resistance of this microarray is one-ninth the resistance of a single electrode with an equivalent surface area. Likewise, the time-constant of the thin-layer cell using the microarray working electrode will improve by a factor of nine compared to the single disk. These results suggest that a fast electrochemical response would be expected when using this microarray in a thin-layer cell. Indeed, when cyclic voltammetry experiments are conducted with the microarray in the thin-layer arrangement, negligible distortion of the current versus potential curve is observed. Importantly, peak current heights obtained with the microarray electrode in the thin-layer arrangement are the same as that obtained under bulk solution conditions. This result indicates that, under the thin-layer condition, the entire surface area of the microarray electrode is available for electrochemical reaction and is participating in the reaction. If the electrode were unevenly polarized, one would expect that only a portion of the electrode surface area would be involved in the electrochemical reaction, and the observed peak currents would be reduced or the current–voltage behavior distorted compared to the bulk electrochemical behavior. This electrochemical result is important because the reflection IR measurement samples the entire surface area of the electrode. To ensure that the spectroscopy results properly represent the electrochemical phenomena, the electrochemical process must be homogeneous across the entire spectral sampling area (e.g. generally the entire electrode surface area in a specular reflection experiment).

Li and Lin describe a reflection IR spectroelectrochemical cell that uses a 10-µm Pt disk as the working electrode. The advantage of using a microelectrode is the small influence that resistance effects have on
microelectrode applications. The small surface area of the working electrode generates very small faradaic currents (nanoamperes to picocamperes). With small currents, even a large thin-layer resistance will have only small influence on potential polarization of the working electrode; consequently, microelectrodes are frequently used in high-resistance applications. This microelectrode cell, therefore, should demonstrate little uneven polarization of the working electrode and have a fast time response. As with the OTTLE thin-layer cells designed by Hartl et al., this microspectroelectrochemical cell places all three electrodes within the solution thin layer (Figure 14). In this arrangement, electrochemistry and spectroscopy measurements could be made on less than 20µL of solution, making this a useful sampling configuration when the sample size is limited. Because of the small dimension of the working electrode, this cell required the tight focus of the IR beam offered by an IR microscope to conduct the spectroelectrochemical experiment.

Although each of these specular reflection cell designs requires the use of a thin layer of solution, all have demonstrated resistance characteristics that are much improved compared to that of a typical OTTLE thin-layer cell. This result suggests that the time response for specular reflection experiments will be sufficient for measurements of dynamic electrochemical phenomena. A rapid electrochemical response is important to specular reflection experiments because electrode potential modulation is one technique that is frequently utilized to improve the signal-to-noise ratio of the spectroelectrochemical measurement.

4.2 Potential Modulation

In specular reflection IR spectroelectrochemistry, one is trying to detect chemical species that are trapped within a solution thin layer, or are present at the electrode–electrolyte interface. Generally this is a very small amount of material, particularly in comparison with the amount of solvent and supporting electrolyte also present in the thin layer. Bewick demonstrated that the signal-to-noise for electrochemically active solutes could be substantially improved by introducing a time variation to the IR spectroelectrochemical experiment. In this first application of specular reflection IR spectroelectrochemistry, a 10-Hz potential modulation was applied to the working electrode. The potential modulation created a continuous oscillation of the identity of the chemical species present within the solution thin layer that was monitored spectroscopically. In many respects, this procedure is analogous to using an optical chopper to introduce a time dependence on the electromagnetic radiation as it arrives at the detector. With the potential modulation, the radiation is being turned on and off at a defined frequency because the interaction between the sample (e.g. the solution thin layer) and the light changes in phase with the potential modulation. The output of the IR detector is directed to a lock-in amplifier that demodulates the detector signal at the frequency of the potential modulation. Consequently, the final output from the lock-in detection is representative of the changes in the IR spectrum of the interface that are in phase with the electrochemical perturbation.

With the potential modulation, the phase-sensitive detection will detect only spectral changes that occur at the frequency of the potential changes. This aspect of the measurement has several important implications to spectroelectrochemical measurements made in this manner. Because detection is at the frequency of the potential modulation, the acquired spectra result from the interfacial reflectance differences at the two potentials of the modulation. The magnitude of the reflectance
INFRARED SPECTROELECTROCHEMISTRY

The spectrum is normally given by Equation (5):

$$\frac{\Delta R}{R} = \frac{R_2(\nu) - R_1(\nu)}{R_1(\nu)} \quad (5)$$

where $R_1(\nu)$ is the interfacial reflectance at applied potential $E_1$ and $R_2(\nu)$ is the reflectance at potential $E_2$. The reflectance spectrum is related to the absorbance by Equation (6):

$$A = -\log \left( \frac{\Delta R}{R} - 1 \right) \quad (6)$$

As a difference spectrum, the appearance is not the same as an absolute spectrum of the thin layer at any given potential. Only those vibrational features that undergo some change caused by the changing value of the applied potential have the same time variance as the potential modulation; therefore, they are the only features that are detected in the IR spectrum. As a result, the baseline of the measurement is at $\Delta R/R = 0$. This reflectance baseline suggests that, for most of the spectral region, there are no changes in the sample brought about by the potential alteration. Considering the spectral contributions from the solvent over most of the available potential window for a given solvent–electrolyte combination, the vibrational features of the solvent will be invariant with the value of the applied potential. Consequently, the solvent contributions to the IR spectrum are effectively cancelled out by measuring the difference spectrum.

A second implication of the potential modulation spectrum is that the final reflectance spectrum will have features with both positive and negative values. The positive and negative features of the difference spectrum arise from changes in the thin-layer reflectances brought about by the two potentials used in the modulation. To illustrate this concept, consider a potential modulation about the standard potential for the oxidation/reduction of some solute. At one potential ($E_1$), the oxidized form is favored within the thin layer. At the other potential ($E_2$), the reduced form is favored. From the $\Delta R/R$ expression (Equation 5), it can be seen that the difference spectrum will have negative-pointing features corresponding to vibrations characteristic of the oxidized form and positive features characteristic of the reduced form. Correlation of the observed spectral features with the potential allows diagnosis of mechanistic aspects of the electrochemical response of the system under investigation. Unlike transmission spectroelectrochemical measurements with the OTTLE cell, the potential changes do not have to convert all of the material within the thin layer. The potential modulation need only create enough of a time-dependent difference in the vibrational modes of species within the thin layer to be observed by the IR spectroscopy. How much of a change is enough depends on the absorptivities of the individual species.

Only those portions of the molecule whose vibrational features are altered by the potential changes are observed. For complex molecules, therefore, the potential modulation method offers the opportunity to identify the site of oxidation/reduction within the molecule (e.g. by observing which vibrational features are most influenced by the potential changes). Although redox conversion of electroactive solutes represents an obvious application of the potential modulation, other more subtle changes brought about by the potential changes may also be observed. Other example applications of processes associated with a changing applied potential include: studies of potential-induced adsorption or desorption of molecules; orientational changes of molecules adsorbed to the electrode interface; changes in the type or strength of adsorption interactions at the interface; changes brought about by the changing electric field strength at the interface and ion migration into or out of the thin layer.

4.2.1 Electrochemically Modulated Infrared Spectroscopy

The initial demonstration of specular reflection IR spectroelectrochemistry by Bewick et al. used a continuous 10 Hz potential modulation and a high-throughput dispersive-IR spectrometer. In this case, the potential modulation was much faster than the rate of wavelength scanning, providing improved signal-to-noise for the measurement. They demonstrated the utility of this method by modulating the oxidation state of thianthrene, and by spectroscopically monitoring the potential-induced adsorption/desorption of indole. The method, which they called electrochemically modulated infrared spectroscopy (EMIRS), provided improved signal-to-noise by having relatively long dwell times at each resolution element of the dispersive spectrometer, and by introducing the time dependence of the spectral signal.

Shortly after its initial demonstration, the EMIRS technique was used to study the electrosorption of methanol. Modulating the electrode potential at 8.5 Hz, two IR features were observed. The first, at 1850 cm$^{-1}$, was attributed to an adsorbed CO at a bridging site, and a complex bipolar band centered at approximately 2070 cm$^{-1}$ was attributed to adsorbed CO bonded to a linear site. The bipolar nature of the band at 2070 cm$^{-1}$ is representative of the changing interfacial properties as the potential is altered. In this case, changes in the IR spectrum of the adsorbed CO with potential alterations provide a probe of the interfacial properties. The shift in the absorption position of the linearly
bonded CO illustrates the subtle changes that arise from the potential modulation that can be monitored by EMIRS.

The power of EMIRS measurements comes from the ability to measure subtle changes within the thin layer that are brought about by the potential change. Although other techniques use the EMIRS method with a dispersive spectrometer, FTIR instruments offer signal-to-noise advantages beyond those obtained by using a potential modulation. When using a scanning FTIR instrument, however, the method of spectral data collection must be modified from that used with EMIRS.

### 4.2.2 Potential Difference Infrared Spectroscopy

With scanning FTIR instruments, a continuous 10-Hz potential modulation is not useful because the sample must be at equilibrium during each interferometer scan. However, potential difference infrared spectroscopy (PDIRS) may still be acquired by synchronizing the potential alteration with the interferometer scans. Two general methods have been used.

In the first potential difference FTIR technique, a small number of interferometer scans are collected at one applied potential, then the potential is changed to a second value and a second set of interferometer data collected. The electrode potential is returned to the first value and this sequence is repeated until a sufficient total number of interferometer scans are collected and co-added at each potential value. The interferograms for each potential value are then Fourier transformed, and the spectrum corresponding to the first potential is ratioed against the spectrum obtained at the second potential and then normalized. In this sequence, the potential is modulated between two values at a frequency that depends on the number of interferometer scans and the individual interferometer scan times. The difference spectra acquired by this technique are equivalent to those obtained by the EMIRS method. As with EMIRS, because the potential is altered between two values repeatedly, the electrochemical response must be reversible with respect to those potential values.

If the electrode response is not reversible with respect to the potential, difference spectra can still be measured, but spectra at individual potentials must be acquired in sequence. Here, the potential is systematically altered and individual spectra are acquired at each applied potential before measuring spectra at the second, third, fourth, etc. potentials. The catalytic decomposition of small organic molecules on Pt has been extensively studied in this manner. After Fourier transformation, any two of these spectra may be ratioed against each other to obtain spectral information regarding changes that occur in the system between these different applied potentials.

An alternative strategy, used by Weaver et al., is to collect spectra as a very slow potential ramp is applied to the working electrode. In this manner, IR spectra are acquired during different time blocks along the potential ramp. Assuming that the spectral acquisition is fast enough (depending on resolution, and interferometer frequency) and/or the potential scan slow enough, during the individual blocks of time the electrode potential changes only slightly. Using this technique, one can obtain a measure of the interfacial dynamics during a continuous, albeit slow, potential scan.

With the exception of the slow potential ramp method used by Weaver et al., continuous-scan FTIR instrumentation requires that spectra be acquired with the chemical system at equilibrium. Consequently, spectral information about fast, dynamic electrochemical phenomena cannot be studied using PDIRS. As described for internal reflection, however, step-scan FTIR instruments provide the opportunity to study dynamic phenomena on relatively short time-frames.

### 4.2.3 Electrochemically Modulated Infrared Reflection Spectroscopy by Step-scan Fourier Transform Infrared

Griffiths et al. have demonstrated the utility of step-scan methods for obtaining spectral information about dynamic electrochemical processes using specular reflection sampling. One application studied the potential dependence of the IR spectrum of adsorbed CO. CO adsorbed on Pt has been extensively studied, providing a wealth of literature for comparison. They found that the signal-to-noise in their step-scan measurements was comparable to data collected by other EMIRS and PDIRS techniques. In addition, the opportunity to conduct a double modulation experiment with the step-scan instrument allowed Griffiths et al. to identify and compensate for the slow time response of the thin-layer cell – effectively using the spectral data and computational methods to correct for the resistance within the thin layer. Although not a critical parameter in these measurements, the opportunity to use the step-scan instrument to determine the level of resistance effects on the electrochemical response is a unique application of the spectral data. As step-scan instrumentation becomes more widely available this may become an important method if quantitative dynamic information is to be extracted from the measurements (e.g. reaction kinetics).

Griffiths et al. also demonstrated that EMIRS experiments using step-scan FTIR can be used to differentiate between species in the bulk solution and those confined to the interface. When demodulating the spectral response due to the continuous potential modulation, the signal may be separated into in-phase and quadrature components. From these components, a magnitude
and a phase spectrum are calculated. When compared, the magnitude spectrum indicates when absorption of the source radiation is occurring and the phase spectrum indicates whether the absorption arises from species in an isotropic (e.g. solution) or a nonisotropic (e.g. interface) environment. Knowing the phase behavior of solution species allows the separation of all of the solution vibrational bands into one of the detection channels (e.g. the quadrature channel), and all the other IR absorptions arising from interfacial species in the other detection channel.\(^{14,15}\) This method provides an opportunity to determine both solution and interfacial species during the same spectroelectrochemical experiment using phase-selective detection. In this case, the contributions from the solution and the interface are separated from each other in the final spectrum.

The combination of the more ideal electrode geometry to reduce the thin-layer resistance, along with the ability to measure and compensate for electrode time delay, suggests that step-scan instrumentation with specular reflection sampling will be a powerful method for studying the dynamics of electrode processes. Although the Griffiths’ method clearly distinguishes solution and interfacial species, alternative methods for separating the interfacial contributions from the solution contributions are also available.

### 4.3 Polarization Effects

Greenler in 1966 demonstrated that specular reflection IR spectroscopy could be used to obtain spectra of thin organic films on metallic substrates.\(^{9}\) Although not initially applied to spectroelectrochemistry, this work established the fundamental principles that govern the experimental aspects of specular reflection IR spectroelectrochemistry today. As with internal reflection methods, the behavior of IR light on reflection from a metallic substrate is determined by solving the boundary value problem for reflection with Fresnel’s equations. This calculation has been conducted for many different systems of relevance to spectroelectrochemical applications, and are not reproduced here.\(^{66,67}\) Only the principal results are discussed, in terms of their influence on sampling and instrumentation in the spectroelectrochemical experiment.

Greenler showed that the mean field strength for the incident radiation maximizes when the IR radiation is incident on the substrate at glancing angles.\(^{9}\) Quantitatively, the mean field strength is calculated by Greenler to be nearly 5000 times larger when the incident light reflects from the surface at 88°, compared to the value obtained for a normal-incidence reflection. In addition, Greenler showed that the sensitivity of the reflection experiment is approximately 25 times larger than that for a transmission experiment using a free-standing film of the same dimension. These calculations were for a thin isotropic organic layer on top of a metallic substrate and exposed to an air atmosphere. Although these results illustrate the utility of the specular reflection technique, they do not realistically model electrochemical systems.

Faguy and Fawcett reproduced Greenler’s calculations assuming a multilayer model that more closely resembles an electrochemical system.\(^{66}\) Their calculations not only accounted for many of the electrochemical parameters, they also considered real instrumental limitations of the spectroelectrochemical experiment; that is, parameters such as the angular divergence of the focused IR beam and the beam focus size were included in the model. In this model, a thin organic layer exists on top of the metallic substrate. The ambient atmosphere is a thin solution layer of some defined thickness (6 µm of acetonitrile was used in their calculations). On top of the solution layer is an initial layer that represents the IR-transparent window (e.g. CaF\(_2\)). This four-layer model allows calculation of the mean electric field strength at the metal interface using conditions that closely approximate the electrochemical experiment.

A result of particular interest from this work was the optimum angle of incidence for maximum field strength at the interface calculated by Faguy and Fawcett for this electrochemical system.\(^{66}\) They found that the optimum angle of incidence for maximum reflectance for these electrochemical systems was not as glancing as reported by Greenler (Figure 15).\(^{66}\) When the angular divergence due to a focusing beam of incident IR radiation is considered, the optimum incident angle is

![Figure 15](image-url)
reduced even further. Faguy and Fowcett’s more realistic electrochemical model also found that the mean field strength is reduced at the interface, compared to values calculated by Greenler. This result indicates that the reflectance for these multilayer systems will be smaller than predicted by Greenler’s model. These results are important because a glancing angle of incidence is a nearly impossible sampling geometry for spectroelectrochemical cells designed for external reflection experiments to attain. With a finite thickness of the solution thin-layer and refraction effects at the boundary between the window and the solution, experimental incident angles of 60–65° are more common. Although Faguy and Fowcett’s calculations predict lower reflectances for real systems, they also show that the angle of incidence typically used in spectroelectrochemical measurements is not as debilitating as expected from Greenler’s work.

In his calculations, Greenler also showed that on reflection from the metallic substrate the phase behavior of the incident light depended on the polarization of the incident light. Light that is polarized perpendicular to the plane of reflection, commonly called s-polarized light, has a near 180° phase shift at the reflection plane for all angles of incidence. Consequently, the incident field strength from the reflected light with perpendicular polarization goes to zero at the interface. Light which is polarized parallel to the plane of reflection, commonly called p-polarized light, has a phase shift that depends on the angle of incidence. For glancing angles, this phase shift is nearly 90°, resulting in an electric field that oscillates normal to the substrate. The result of this phase behavior is that, on reflection, the incident radiation generates a field at the interface that is oriented normal to the metallic substrate. This polarization dependence at the interface generates what has commonly been referred to as the surface selection rules. That is, only those vibrational motions for confined species with a component of their transition dipole moment change that lies perpendicular to the substrate are observed. This is due to the electric field from the incident radiation being present only in a direction normal to the substrate. There are a number of important experimental consequences that come from this result.

Discrimination between solution-phase material and adsorbed species can be obtained by comparing spectra collected using polarized incident radiation. When the incident light is fixed so that its electric field is oriented parallel to the plane of incidence (p-polarized), the resultant spectrum contains information about species present in both the bulk solution and those confined to the interface. Repeating the experiment with the incident light polarized perpendicular to the plane of reflection results in spectra that contain information only about species in the bulk solution. These results are due to the directional aspect of the interfacial electric field. Species present in the solution are randomly oriented and can interact equally with the p- and s-polarized light. When confined to the interface, species can only interact with incident radiation that has p-polarization. Comparison of spectra, obtained under identical conditions with the exception of the polarization of incident light, allows identification of those vibrational modes that arise from confined versus solution-phase material. Foley et al. demonstrated this effect when investigating the potential induced adsorption of SCN⁻ by specular reflection PDIRS.\(^{(56)}\)

For systems in which only species confined to the interface are studied, the spectral signal-to-noise ratio may be increased by a factor of two by using incident radiation that is only p-polarized. This is understood by considering the behavior of p- and s-polarized light at the interface. p-Polarized light is able to interact with the confined material; consequently, it will possess spectral information as well as random noise. Incident light that is s-polarized has no interaction with species confined to the electrochemical interface. Consequently, it will contain no spectral information about the confined species, but will carry random noise. By filtering the s-polarized light, 50% of the noise contribution has been eliminated without affecting the spectral signal.

Evaluation of the reflection IR spectrum of a material confined to the interface relative to its isotropic bulk spectrum can also provide information about the orientation/structure of the molecule at the interface. Although not an electrochemical application, Allara and Nuzzo illustrate the principle of this analysis when characterizing the structure of long-chain surfactants adsorbed on metallic substrates.\(^{(68)}\) From the results of a Kramers–Kronig evaluation of an IR spectrum of a randomly distributed isotropic sample, a theoretical reflection spectrum of the sample can be obtained. The calculated reflection spectrum assumes that the adsorbed layer is homogeneous, isotropic and has the same structure as found in the bulk. If the interfacial structure is anisotropic, the experimental reflection spectrum will differ from the theoretical spectrum by the intensity of the vibrational modes. These intensity differences arise from the anisotropy of the sample and the directional aspect of the incident field strength at the interface. Comparison of this calculated, theoretical spectrum with the actual experimental reflection spectrum allows evaluation of the average orientation/structure of the molecules when they are confined to the interface.

### 4.3.1 Reflection Losses

Although polarization behavior on reflection from the electrode surface provides valuable information regarding surface-confined species, care must be taken to ensure
that the experiment does not introduce polarization artifacts. Just as the two polarizations have different reflectivities from the electrode, they also reflect with different efficiencies from other surfaces. It is possible, therefore, that the optical path of the instrument may introduce some differential polarization of the source radiation. For example, the different polarizations of light may reflect with different efficiencies from the front surface of the IR-transparent window of the spectroelectrochemical cell. For a flat disk-shaped window, the amount of light that is transmitted through the window depends on the incident polarization as well as the angle of incidence. When using a glancing angle, light polarized perpendicular to the reflection plane reflects from the window and is not as efficiently transmitted through to probe the electrochemical interface as is light polarized parallel to the reflection plane. Using a trapezoidal or hemicylindrical prism as the window may circumvent this problem. With prism windows, the IR light has normal incidence at the ambient–window interface and each polarization is transmitted with equal efficiency. Differential polarization induced by the instrument or sample cell is of particular concern when using a continuous polarization modulation for spectral sampling.

4.3.2 Polarization Modulation

Like potential modulation, one can use a continuous polarization modulation to effectively cancel out those portions of the spectrum that are invariant to the polarization of light. Unlike potential modulation, however, the incident light polarization may be modulated at a frequency high enough that this modulation method may be coupled to scanning FTIR spectral data acquisition. Conceptually, polarization modulation takes advantage of the surface selection rules to differentiate between the interphase and the bulk. Species in the bulk solution are equally likely to interact with p- and s-polarized light depending on the incident polarization as well as the angle of incidence. When using a glancing angle, light polarized perpendicular to the reflection plane reflects from the window and is not as efficiently transmitted through to probe the electrochemical interface as is light polarized parallel to the reflection plane. Using a trapezoidal or hemicylindrical prism as the window may circumvent this problem. With prism windows, the IR light has normal incidence at the ambient–window interface and each polarization is transmitted with equal efficiency. Differential polarization induced by the instrument or sample cell is of particular concern when using a continuous polarization modulation for spectral sampling.

$$\frac{\Delta R}{R} = \frac{R_p - R_s}{R_p + R_s}$$

where $R_p$ is the sample reflectance obtained with the p-polarized incident radiation and $R_s$ is the sample reflectance obtained with the s-polarized radiation. It is obvious from this equation that species that have equal interaction with both p- and s-polarized light (e.g. bulk-phase material) will cancel in the final reflectance spectrum, whereas those with differential reflectivity will be observed. Consequently, the final reflectance spectrum will contain spectral information about only the interfacial region.

Typically the phasing behavior is thought to predominate in the region of space extending a distance approximately one-quarter of a wavelength away from the substrate into the solution. In the mid-IR region of the spectrum, therefore, the polarization modulation experiment samples approximately the first 1.5–2.5 $\mu$m into the solution away from the substrate. For a well-aligned spectroelectrochemical cell, this sampling dimension can be up to 50% of the total thin-layer thickness. Although sampling by polarization modulation does not discriminate entirely against solvent in the thin layer, it does isolate a smaller region of the interphase. This results in an overall enhancement of the spectral signal-to-noise. This provides the possibility, under the correct experimental conditions, of monitoring by IR spectroscopy the diffusion behavior at the interface. Combining polarization modulation with a potential modulation scheme, as Kunimatsu et al. demonstrate, provides excellent signal-to-noise for monitoring the potential-dependent behavior of adsorbed molecules.

There have been several experimental demonstrations of the utility of polarization modulation to electrochemical systems. Kunimatsu et al. used the technique to study the adsorption of CO to Pt electrodes. Anderson and Gatin investigated the structural behavior of self-assembled monolayers when potential is applied to the substrate. Saez and Corn investigated the structure of polymer films deposited on electrodes as a function of electrode potential.

4.3.3 Photoelastic Modulator

To conduct the polarization modulation experiment, the polarization of the incident radiation must be rapidly alternated between the linear p- and s-polarization extremes. The frequency of this polarization modulation must be fast relative to the frequency of the interferometer frequency in order to separate the signal modulation due to the polarization from that due to the scanning interferometer. This separation of the two time-dependent signals is possible if the light polarization is modulated at a high frequency relative to the frequency of the interferometer. An instrument called a photoelastic modulator provides this high-frequency dynamic change in the incident light polarization state.

Construction of the photoelastic modulator was first described in 1966. Hipps and Crosby have described the principle of the dynamic polarization of light by photoelastic modulation. The optically active portion of the photoelastic modulator is an isotropic crystal
of some material transparent in the spectral region of interest. For IR measurements, instruments that use CaF$_2$ and ZnSe crystals are commercially available. A periodic stress is applied to the isotropic crystal with a physical transducer, generally a piezoelectric material bonded to the stress axis of the IR-transparent crystal (Figure 16). This mechanical stress induces a strain in the crystal along this axis. The strain in the crystal induces a variation of the optic ellipsoid of the crystal material at a resonance frequency.

As seen in Figure 16, the incident radiation is linearly polarized prior to passing through the photoelastic modulator. The electric field of the incident linear polarized light is aligned $45^\circ$ away from the crystal strain axis. The strain is driven sinusoidally at the resonance frequency of the crystal, so the refractive index of the crystal along this axis varies sinusoidally as well. The refractive index change creates a time dependent phase shift of the incident light, which is given by Equation (8),

$$\phi = \phi_0 \cos(\omega t)$$  \hspace{1cm} (8)

where $\phi_0$ is the maximum phase shift ($180^\circ$), $\omega$ is the resonant frequency, and $t$ is time. When linearly polarized light passes through the photoelastic modulator crystal, the light emerges elliptically polarized due to the strain-induced phase shift. Dependent on when during the stress–strain cycle the light emerges, the polarization of the emerging light changes between linear polarization and different degrees of elliptical polarization. If the maximum phase shift ($\phi_0$) is $180^\circ$, then during a complete strain cycle the polarization of the light emerging from the modulator goes through two complete cycles of linear p- to linear s-polarized light (which are $90^\circ$ out of phase from each other).

The intensity of the light that reaches the detector after passing through the photoelastic modulator and reflecting from the metallic substrate is given by Equation (9): \hspace{1cm} (9)

$$I_d = C \frac{I_0(w)}{2} \{ (R_0 + R_s) - 2(R_0 - R_s)J_2(\phi_0) \cos(2\omega t) \}$$

where $C$ is a constant, $I_0(w)$ is the light intensity as it enters the photoelastic modulator, $J_2(\phi_0)$ is a second-order Bessel function, and all other terms have their normal meaning. The second-order Bessel function originates from the wavelength dependence of the peak efficiency from the polarization modulation. Strictly, the photoelastic modulator will only modulate the polarization of the light between the linear p- and s-polarized extremes for a single wavelength. This wavelength is determined by the potential used to drive the strain of the modulator crystal. That is, the maximum phase change, $\phi_0$, is given by Equation (10): \hspace{1cm} (10)

$$\phi_0 = \frac{GV}{\lambda}$$

where $G$ is a constant value, $V$ is the strain driving voltage, and $\lambda$ is the wavelength of peak polarization retardation. For a given drive voltage, therefore, only one wavelength will have the maximum phase shift. For all other wavelengths, the polarization states during the mechanical strain cycle are elliptical.

Seki et al. investigated this wavelength dependence of the polarization state and its influence on distorting the measured IR spectrum. Although the polarization modulation is only accurate for a single wavelength, they found that the elliptical light does not dramatically

---

**Figure 16** Diagram of the optical path used in the polarization modulation FTIR experiment. Illustration of the linear to elliptical polarization change as the linearly polarized light passes through the photoelastic modulator. (Reprinted from T. Buffeteau, B. Desbat, J.M. Turlet, ‘Polarization Modulation FTIR Spectroscopy of Surfaces and Ultra-thin Films: Experimental Procedure and Quantitative Analysis’, *Appl. Spectrosc.*, 45(3), 380–389, copyright (1991) with permission from the Society for Applied Spectroscopy.)
distort the measured spectrum in the wavelength region surrounding modulation wavelength. For example, if the retardation of the photoelastic modulator is set at 2100 cm\(^{-1}\), the multiplication factor from the Bessel function varies from 1 (at 2100 cm\(^{-1}\)) to 0.8 (at 1450 cm\(^{-1}\) and 2600 cm\(^{-1}\)) within the range 1450–2600 cm\(^{-1}\). Over this wavenumber region with this limited distortion, the Bessel function can be approximated by a parabola, fit to the baseline, and then subtracted from the polarization modulation spectrum.

4.3.4 Detection of Polarization Modulation/Fourier Transform/Infrared Reflection–Absorption Spectroscopy

As stated before, the different polarizations of light will reflect from surfaces with different efficiencies. In the polarization modulation experiment, after the source radiation passes through the photoelastic modulator it should reflect from only one surface (e.g. the surface being characterized). This ensures that the spectral information encoded by the differential reflectivity at the interface of interest is not mixed with polarization effects at other reflections. Consequently, lenses are used to collect and focus the light after reflecting from the interface of interest in the polarization modulation experiment. In cases where mirrors are used after the sample reflection, a plate of some IR-transparent material (e.g. KBr) is placed into the optical path and at an angle relative to the direction of light propagation. This plate offsets any polarization discrimination due to reflection differences from the optics of the instrument. Although this optical compensation works to balance polarization differentiation that occurs within the optics of the instrument, it is inefficient because it throws away some of the source radiation.

Polarization modulation reflection–absorption spectroscopy using FTIR instrumentation is a double modulation experiment. As such, the frequency components of these two modulations need to be sufficiently disparate so that they may be effectively separated by lock-in detection. A typical IR photoelastic modulator operates at a frequency of 74 kHz. The spectral information from an FTIR instrument operating under normal conditions contains frequencies ranging from a few hertz to tens of kilohertz. The upper range of the spectral frequencies is too close to the frequency of the polarization modulation by the photoelastic modulator for efficient separation by lock-in detection. Lowering the scan speed of the interferometer increases the difference between the spectral frequency and the polarization modulation frequency to allow lock-in detection. The ultimate decrease in the interferometer frequency is accomplished using a step-scan interferometer where the discrete steps of the interferometer moving mirror reduce the instrument frequency to essentially zero.\(^{15}\) Highly sensitive detectors, such as HgCdTe and InSb, operate most efficiently when there are fast changes of the IR light intensity incident on them. Decreasing the interferometer scan speed lowers the efficiency of these detectors. Lowering the scan speed of the interferometer also lowers the stability of the interferometer and increases the level of noise in the measured spectrum. Although lowering the interferometer scan rate is often required for detection with a lock-in amplifier, it does come at the cost of lower spectral signal-to-noise. To efficiently collect the double modulation spectra with a continuous scan FTIR instrument, the rise time of the lock-in amplifier must be short, requiring a short time constant of the lock-in amplifier instrument (below 1 ms). This requirement places additional constraints on the instrumentation required for these measurements. Nevertheless, polarization modulation FTIR methods using lock-in detection have been demonstrated, and have been used in several spectroelectrochemical applications.\(^{49,57,69}\)

Corn et al. developed electronics that allow real-time sampling for the acquisition of FTIR spectra during the double modulation experiment.\(^{74,75}\) Unlike demodulating the frequency components of the experiment with a lock-in amplifier, these electronics do not require that the two modulation frequencies have a large difference. The instrument provides an accurate separation of the high-frequency component of the polarization modulation from the slower spectral frequency of the interferometer. Consequently, the interferometer can be operated using normal scan rates during the spectroelectrochemical experiment. This improves the overall signal-to-noise of the polarization modulation experiment because the interferometer is stable at the higher scan rates, and because the IR detectors operate more efficiently at the higher scan rates. Several spectroelectrochemical applications of the real-time sampling electronics have appeared. Richmond et al. acquired spectrochemical data for the adsorption of thiocyanate, imidazole, and glucose using real-time sampling electronics with the polarization modulation method as well as a static polarization technique. They found that the spectra were virtually identical, but that the real-time electronics provided better rejection of the solvent and better overall signal-to-noise.\(^{76}\) Real-time sampling of polarization modulation FTIR experiments has also been used to monitor water and hydroxide vibrations associated with the interface.\(^{77}\) This is an extremely challenging spectroscopic measurement because of the presence of water as the bulk solvent in the thin layer. The properties of the polarization modulation experiment provide the sensitivity and ability to discriminate against the bulk required to make these types of measurements.
5 SUMMARY

As illustrated throughout this article, the combination of IR spectroscopy and electrochemistry is an area of active research interest. The two experiments provide complementary information. Conducting the two measurements simultaneously provides insight about the chemical system that could not be obtained otherwise. The principal issues faced when conducting these simultaneous determinations are spectral sampling of the electrochemical system, and the overall signal-to-noise of the measurement. The three dominant sampling methods have unique strengths and weaknesses. Interestingly, these three methods tend to be complementary to each other, each having strengths in different areas. The type of information desired from the spectroelectrochemical experiment therefore dictates the sampling method used.

Sensitivity advances in the field of IR spectroelectrochemistry have followed improvements in the instrumentation available for the measurements, and this is likely to continue to drive the area. Modulation techniques introduce a time-variant signal that allows use of phase-sensitive detection methods to improve the sensitivity of the measurement. Polarization modulation methods help to isolate the interface, enhancing the sensitivity for double-layer phenomena. The availability of step-scan FTIR instrumentation allows use of a wider range of modulation frequencies that were not previously available for spectroelectrochemical experiments with traditional scanning FTIR instrumentation. These developments have made accessible for spectroelectrochemical measurement those phenomena that occur at the electrode interface and at short times after initiating the electrochemical experiment. New challenges continue to appear that can benefit from IR spectroelectrochemical measurements.

1 Introduction

1 INTRODUCTION

Potentiometry is a static, interfacial electroanalytical technique that has found acceptance across a wide range of disciplines. This is due in large part to the development of ISEs. In the most recent recommendations of IUPAC, an ISE is defined as follows: (1)

This is an electrochemical sensor, based on thin films or selective membranes as recognition elements, and is an electrochemical half-cell equivalent to other half-cells of zeroth (inert metal in a redox electrolyte), 1st, 2nd and 3rd kinds. These devices are distinct from systems that involve redox reactions (electrodes of zeroth, 1st, 2nd and 3rd kinds), although they often contain a 2nd kind electrode as the ‘inner’ or ‘internal’ reference electrode. The potential difference response has, as its principal component, the Gibbs energy change associated with permselective mass transfer (by ion exchange, solvent extraction or some other mechanism) across a phase boundary.

As indicated by this definition, one surface of the thin film or membrane is in contact with a bulk phase whose composition may be varied. The “heart” of an ISE is its thin film or membrane. Thus, much of the research in this area has involved a search for or the fabrication of thin films or membranes that are highly selective for a single ion. The ideal thin film or membrane is one that is specific for a single ion. The actual thin film or membrane, designed to target a single ion, called the analyte, is selective for a small set of ions. The ions left in the set after the analyte ion is removed are called electrode interferences. For example, the lithia-based glass membrane pH electrode targets H\textsuperscript{+}, but is selective for \( \text{Li}^+, \text{Na}^+ \). Its electrode interferences are \( \text{Li}^+, \text{Na}^+ \). For the glass membrane pH electrodes, the electrode interferences are serious problems only when they are at fairly high concentrations. This is the exception, rather than the rule.

Electrode interferences are by no means the only interferences that one encounters in working with these devices. Chemical interferences may be of equal or even greater importance than electrode interferences. Chemical interferences are species that either tie up the analyte ion or that change the membrane so that it can no longer effectively interact with the analyte. These types of interferences are very dependent on the type of active material constituting the membrane. Thus a second area of research in the field of ISEs has involved identifying various interferences and quantifying their effects on an ISE’s signal, since interferences affect how and when various ISEs may be used.

ISEs are now being exploited as detectors in flow injection analysis systems. In such systems, the dynamic

---

This article begins with an introduction to ion-selective electrodes (ISEs). The classification protocol based on the most recent International Union of Pure and Applied Chemistry (IUPAC) recommendations is given. The historical development of ISEs is summarized, starting with the pH electrode. For the inorganic cations and anions, a periodic table “time-line” is given. Recent history has seen the rise of polymer membrane ISEs, which are important in clinical analysis. The historical section concludes with a brief look at these ISEs. The general theory of the potential generation process is explained, and then aspects of the potential generation process that are specific for the different classes of ISEs. A short review of the instrumentation needed to make the measurements is given, followed by an overview of the latest commercially available instrumentation. One aspect of ISE research is the development of selective probes for determining the analyte content of individual cells. This requires miniaturization, and this has been achieved by the development of microelectrode ISEs. An overview of this area is given. Finally, some recent developments that represent the directions of research in the ISE field are given. Included are the development of sensors for patient monitoring, the development of ISE sensor arrays, and the development of more sophisticated electronic and mathematical methods of data analysis.
behavior of the ISE assumes great importance, since that will determine the signal shape and the sampling rate. Characterizing the dynamic behavior of ISEs constitutes a third area of research in the field.

For the most part, research in these three areas has unfolded in the order given. For example, when a new membrane was developed, the obvious electrode interferences were examined. However, many interferences were identified only after researchers tried to develop applications in various disciplines. Because of the way in which early analyses were done, the dynamic response of an ISE was not of extreme importance. The response rate had to be rapid enough that potentiometric titration curves would not be distorted. For direct analysis, one could simply wait for the signal to stabilize.

This field has just passed its golden anniversary. So many membranes have been developed that a classification scheme had to be recommended. The membranes will be introduced by means of the latest classification scheme. After a short delineation of the historical development, the theory of the electrode response will be presented. Both the equilibrium and the dynamic response behavior in the absence and presence of interferences will be discussed. Instrumentation has played a very large role in the ascendency of this field. The instrumentation requirements will be discussed, and then some of the most recent instrumentation will be presented. Physiological and biological applications of ISEs have been a goal since the inception of the field. Now, miniaturization in instrumentation seems to be a current paradigm. ISEs are part of this effort, as researchers have and continue to develop ion-selective microelectrodes for intracellular measurements of ion activities. The progress in this area will be summarized. Finally, some recent, novel developments in this field will be reported, particularly those which may find commercial applications within the next 10 years. In this article, only a very small part of a vast literature can be included. However, the journal Analytical Chemistry has published a series of review articles that include ISEs.2, 24 They are an excellent place to start a search for more detail on a specific topic. For the most part, physiological and biological applications of ISEs involve the use of carrier-based microelectrode ISEs. These have been comprehensively reviewed by Bakker et al.25

In the new classification scheme, the old scheme is retained as a single category, primary ISEs. Two new categories, compound or multiple membrane ISEs and metal contact or all-solid-state ISEs, have been added. None of these categories include the ISFET (ion-selective field effect transistor) or CHEMFET (chemical-sensing field effect transistor), because they are considered to be purely capacitatively coupled devices.27 However, some of these devices are commercially available, and they are called “electrodes” by their vendors.28 It should be noted that some researchers have argued that the glass membrane ISEs are capacitative devices.29, 30 The experimental results that are the basis of their conclusions have not been independently verified. If true, the glass membrane ISE would be a half-cell for an electrochemical capacitor. The development of electrochemical capacitors is a fairly new field; the United States Department of Energy has had such a program since 1992.31 The electrochemical capacitor is just a third type of electrochemical cell. Should it be shown that at least one ISE is a half-cell for an electrochemical capacitor, then we might expect a future classification scheme to include ISFETs or CHEMFETs. Reproduced below is the classification scheme according to the IUPAC 1994 recommendations.31

A. Primary ISEs

1. Crystalline electrodes
   (a) Homogeneous membrane electrodes
   (b) Heterogeneous membrane electrodes

2. Non-crystalline electrodes
   (a) Rigid, self-supporting, matrix electrodes
   (b) Electrodes with mobile charged sites
      – Positively charged, hydrophobic cations
      – Negatively charged, hydrophobic anions
      – Uncharged carrier electrodes
      – Hydrophobic ion-pair electrodes

B. Compound or Multiple Membrane ISEs

1. Gas-sensing electrodes
2. Enzyme substrate electrodes

C. Metal Contact or All-solid-state ISEs

Examples of the constructions used for the three main categories are shown in Figures 1–3. Gas-sensing electrodes consist of a reference electrode and indicator electrode that are in electrolytic contact. Some researchers say that these devices should not be called electrodes, because they are really electrochemical cells.32 An ordinary ISE is used by placing it in a solution containing the analyte ion and measuring the potential, using a high-impedance potentiometer circuit, with respect to a reference electrode, placed in the same solution. The reference electrode, analyte solution and ISE constitute an electrochemical cell.

Many ISEs may now be purchased as combination electrodes. A combination electrode consists of an ISE and a reference electrode in a single package. An example
of a combination electrode, the Orion glass pH electrode, is shown in Figure 4. Some researchers would probably argue that a combination electrode is not really an electrode. If one immerses it in an analyte solution, then one has an electrochemical cell. An analogy is the conventional car battery without the electrolyte. We do not regard it as an electrode just because the electrolyte is missing. For the foreseeable future, the use of the term combination electrode will undoubtedly continue. Technically correct and noncumbersome nomenclature for these devices does not exist at present.

2 HISTORICAL DEVELOPMENT

It is generally agreed that the progenitor of ISEs is the glass membrane acidity electrode. Cremer is credited with making the discovery that a large potential difference exists across a thin glass membrane in contact with solutions with large differences in acidity on opposite sides of the membrane. It is fascinating to note that Cremer’s work was actually the culmination of many studies on the electrical properties of glasses starting as far back as 1761! At that time, glasses were considered to be materials that consisted of silicon dioxide and various other oxides. The properties of the glasses were known to depend on which other oxides were added and on the stoichiometry of the resultant material. Thus, some glasses were shown to be conductors of electricity, while others were shown to be electrical insulators. Cremer, who was interested in the potential differences generated across certain biological tissues, recognized that the Warburg model of glass meant that it should be an ideal semipermeable membrane. He performed several experiments using a flask containing an electrolyte solution immersed in a beaker, also containing an electrolyte solution. A platinum wire was in contact with
each solution. He found that when the two electrolytes differed in their acidities, a large potential difference could be measured across the two platinum electrodes.

Systematic, quantitative studies on this phenomenon were made by Haber and Klemensiewicz on glass bulb electrodes.\(^{(35)}\) In that paper, the theoretical model for the electrode response was developed by Haber, and the experimental confirmation of the model was performed by Klemensiewicz. For the theoretical model, Haber extended the work of H.W. Nernst.\(^{(36)}\) Of particular relevance to the development of the mathematical form for the electrode potential of an ISE is Nernst’s treatment of the potential difference across the interface between two electrolyte solutions, the well-known liquid junction potential, generated by non-Faradaic processes. He showed that the steady-state potential difference across an interface between a dilute solution of HCl (concentration \(c_1\)) and a more concentrated solution of HCl (concentration \(c_2\)) has the form of Equation (1):\(^{(36)}\)

\[
E = \frac{RT}{3} (t_+ - t_-) \ln \left( \frac{c_1}{c_2} \right)
\] (1)

where \(E\) is the potential of the interface on the side of the more concentrated solution relative to the more dilute solution, \(t_+\) is the transport number for the cation, and \(t_-\) is the transport number for the anion and \(\Delta\) is Faraday’s constant. (Note that in this and other equations, the expressions for \(E\) have been written in modern form. In the original equations, \(R\), the gas constant, is given in electrical dimensions. In modern usage, \(R\) is given in energy dimensions. \(R\), in electrical units, is equal to \(R\) in energy dimensions divided by the Faraday constant \(\Delta\).)

To verify his theory, Nernst studied concentration cells of the form in Equation (2):

\[
M[MX(c_1)]MX(c_2)]M
\] (2)

where \(MX\) is a strong electrolyte and \(c_1 \neq c_2\). Here, Nernst proposed that the mathematical relationship for the potential difference across the metal electrolyte interface under conditions of zero current flow is given by Equation (3):\(^{(36)}\)

\[
E = \frac{RT}{3} \ln \left( \frac{C}{c} \right)
\] (3)

where \(C\) is the concentration of ion cores in the metal and \(c\) is the concentration of the electrolyte. According to Nernst, dissolution of the metal may occur, such that ions cross to the solution side and electrons remain in the metal, or metal ions from the electrolyte may specifically absorb on the metal surface. These processes are also non-Faradaic. Thus Nernst clearly proposed that his mathematical treatment was a general one valid for all electrified interfaces under conditions of equilibrium or steady-state charge transport. Haber extended Nernst’s treatment to the case of a concentration cell involving a solid electrolyte MX and an aqueous electrolyte MX, with the cell notation as in Equation (4):

\[
M[MX(s)]MX(aq)]M
\] (4)

He showed that the potential at the interface between the aqueous and the solid electrolytes is given by Equation (5):

\[
E = -\frac{RT}{3} \ln(C_M) + K
\] (5)

where \(C_M\) is the concentration of the metal ion in the aqueous electrolyte solution and \(K\) is a constant. Haber then proposed that a hydrated glass membrane is a type of solid water phase. By considering the cell in Equation (6):

\[
H_2|H_2O(s)|H_2O(l)|H_2
\] (6)

he arrived at Equation (7) for the potential difference across the glass membrane – water interface:

\[
E = -\frac{RT}{3} \ln(C_{H_2}) + K
\] (7)

where \(C_{H_2}\) is the concentration of hydronium ions and \(K\) is a constant. Similarly, by considering the cell in Equation (8):

\[
O_2|H_2O(s)|H_2O(l)|O_2
\] (8)

he arrived at a second expression for the potential difference across the glass membrane – water interface (Equation 9):

\[
E = +\frac{RT}{3} \ln(C_{OH^-}) + K'
\] (9)

where \(C_{OH^-}\) is the concentration of hydroxide ions and \(K'\) is a constant. We see that Haber recognized that the glass membrane can sense either hydronium ions or hydroxide ions. He further indicated that Equation (9) could be written in terms of \(C_{H^+}\) by making use of the relationship \(C_{OH^-} = K_w/C_{H^+}\), giving Equation (10):

\[
E = -\frac{RT}{3} \ln(C_{H^+}) + \frac{RT}{3} \ln(K_w) + K'
\] (10)

Haber then stated that Equations (7) and (10) are identical, which meant that \(K\) and \(K'\) are related by Equation (11):

\[
K = \frac{RT}{3} \ln(K_w) + K'
\] (11)

Haber’s statement, given without proof, was widely accepted by subsequent analytical chemists. Later, in
where \( C_{\text{KOH}} \), \( 0.1 \text{ N HCl with 1 N NaOH} \), \( 0.1 \text{ N H}_2\text{SO}_4 \) with 1 N NaOH, \( 0.1 \text{ N KOH with 1N HCl} \). The potential of the glass membrane electrode was measured with respect to the normal calomel electrode using a quadrant electrometer with reading telescope. Plots of the potential difference versus volume of titrant gave the typical sigmoidal curves that are well known to us today. The magnitude of the potential difference between the initial point of the titration and the final point of the titration, which corresponded to an extent of titration = 2, is expected to be given by Equation (13), with the final point corrected for dilution effects and the ratio of the concentrations of hydronium ion being that for the acidic solution to that for the basic solution. For titrations involving KOH, the experimental error for titrations performed at 20 °C averaged −7%, which is fairly good. When KOH was replaced with NaOH, much larger relative errors were obtained, −15 to −22%. This came to be known as the sodium error. Titration of a weak acid with a strong base was also performed; it showed the characteristic sigmoidal curve with the buffer region so familiar to us today.

The effect of temperature was also studied, as was the effect of the glass on the potential generation. Two other easily fusible glasses, one a blue-colored, silicic acid-poor and sodium-rich glass and the other a colorless, silicic acid-rich and alkali-poor glass, were studied. The freshly blown blue-colored glass gave a relative error of −14%, but after steam treatment the error increased to −51%. The error for the colorless glass was even worse, being −57% for freshly blown and −71% for steam treated. When difficult to fuse Jena glass was used, no potential difference developed. Although the glass studies were qualitative at best, since the compositions were not measured, these results opened the way to what soon became an explosion in the development of ISEs.

Around this same time, Størenson proposed the pH scale for acidity measurements\(^{37}\) and the glass membrane acidity electrode ultimately came to be known as the pH electrode. From 1920 to 1935, quantitative studies on the effect of glass composition on the potential generation for the acidity electrode proliferated.\(^{38}\) The compositions of Thuringian glass and the Jena glasses were determined.\(^{39}\) This period was capped by the development of the first commercial pH glass manufactured by Corning as Corning 015 glass.\(^{40}\) Because this glass composition was not ideal for the entire range of the pH scale, studies on glass composition for pH electrodes continued, with the results for over 500 different compositions appearing in the literature.\(^{41}\) The sodium error results seem to have led some researchers to search for glass compositions that would give glass membranes sensitive to other ions. Thus, in 1934, Lengyel and Blum\(^{42}\) reported on a glass
membrane electrode that gave a Nernstian response to sodium ions. Subsequent glass composition studies by Eisenman,\textsuperscript{(43)} reported in 1957, led to commercial glass membrane electrodes for sodium and potassium ions.

It is interesting that materials other than glass were reported as active materials for potentiometric ion sensors in the period from 1930 to 1960. These included inorganic sparingly soluble salts, surface-modified collodion, and cation-exchange resins for ions such as Ca\textsuperscript{2+}, Na\textsuperscript{+}, K\textsuperscript{+}, NH\textsubscript{4}\textsuperscript{+}, Mg\textsuperscript{2+}, Ag\textsuperscript{+}, Cl\textsuperscript{−}, Br\textsuperscript{−}, I\textsuperscript{−}, Ba\textsuperscript{2+}, ClO\textsubscript{4}\textsuperscript{−}, NO\textsubscript{3}\textsuperscript{−}, and SO\textsubscript{4}\textsuperscript{2−}.\textsuperscript{(44)} At the time, this research seems to have been ignored, largely because of irreproducible results and lack of a Nernstian response. Glass membrane studies continued, and additional glass membrane electrodes were developed for Li\textsuperscript{+}, Ag\textsuperscript{+}, NH\textsubscript{4}\textsuperscript{+}, Rb\textsuperscript{+} and Cs\textsuperscript{+}. In the 1960s, studies by Pungor et al.\textsuperscript{(45)} led to the first nonglass ISEs to give thermodynamically reversible responses—sparingly soluble inorganic salts in silicone rubber. These were commercialized and marketed by Radelkis in Hungary in 1965. Up to this point, cation ISEs with acceptable responses existed only for univalent ions.

By contrast, the development of ISEs for organic and bio-organic analysis is now experiencing the kind of growth that was observed for inorganic ions from 1960 to 1979. This era seems to have commenced with the development in 1969 of the urea ISE by Guibault and Montalvo,\textsuperscript{(50)} the development in 1972 of coated-wire ISEs for amino acid anions and salicylate by James, Carmack and Freiser\textsuperscript{(51)} and the development in 1972 of PVC matrix membrane ISEs for large onium ions by Scholer and Simon.\textsuperscript{(52)}

Electrodes have now been reported for glucose, L- and D-aspartic acids and their methyl esters, 1-phenylethylamine, 1-(1-naphthyl)ethylamine, ephedrine, norephedrine, pseudoephedrine, amphetamine, propanolol, α-amino-ε-caprolactam, amino acid amides, benzylamine, alkylamines, dopamine, procaine, prilocaine, lidocaine, bupivacaine, lignocaine, diquat, paraquat, acetylcholine, albumin, amygdalin, penicillin, protamine, catechol, cholesterol, creatinine, uric acid, 5'-AMP, glutamine, glutamate, pyruvate, vitamin B\textsubscript{6}, guanine, guanidine, amprolium, heparin, methotrexate, mexiletine, mexiteline, metformin, phenformin, clotrimazole, bifonazole, human immunoglobulin G, organohosphate nerve agents, cationic surfactants, anionic surfactants, and organosulfonates.\textsuperscript{(25,50–63)} Only the glucose, urea and creatinine electrodes are available commercially.

The first gas-sensing ISE was the carbon dioxide gas electrode, conceptualized in 1957 by Stow, Baer and Randall.\textsuperscript{(64)} After a 10-year gap, the ammonia gas-sensing electrode was developed, and by 1976 electrodes had been developed additionally for NO\textsubscript{3}, SO\textsubscript{2}, H\textsubscript{2}S and CH\textsubscript{3}COOH.\textsuperscript{(64)} As shown in Figure 7, 10 gas sensing ISEs are now available commercially. Further development in this area is not likely, because acoustic wave devices with higher sensitivities, faster responses, and simpler construction are likely to become the sensors of choice for gas analysis.\textsuperscript{(65)}

3 THEOREY OF ELECTRODE RESPONSE

3.1 General

All of the ISEs share in common that the component of the measured signal which is related to the activity of the analyte to be determined is the potential difference across interface 1 in Figure 8(a) or (b). Figure 8(a) is the configuration for the primary ISEs. Figure 8(b) is the configuration for the metal contact or all-solid-state ISEs. The compound or multiple membrane ISE has an
Since electron density is proportional to the product of a wave function and its complex conjugate, this means that some electrons have spilled across the solid surface and into the vacuum. However, these electrons belong to the solid, and not the vacuum (i.e. ionization has not occurred). Thus, all solids in a vacuum have a surface dipole barrier at the interface between the surface and the vacuum. The magnitude of the surface dipole barrier would be largest for a free electron metal and smallest for an insulator. In the case of an ionic solid, surface defects are the source of the equilibrium space charge potential.

### Figure 6
Periodic table profile for the historical development of ISE membranes for inorganic ions.
are orientated so that a lone pair on the oxygen points toward the vacuum than are oriented with the hydrogens pointed toward the vacuum. Thus the picture for the surface dipole barrier is analogous to that for the solid. These surface dipole potentials are often called the “chi potentials”.

Now, if the semi-infinite solid and the semi-infinite electrolyte solution are brought together and no transfer of charge occurs between them, the two phases remain neutral, but the interface between them is electrified owing to the difference between their surface potentials. The potential difference will be smaller than the numerical difference between the two vacuum referenced values, because there will be a readjustment of the electron density on the solid side, the distribution of defects, the orientation of water dipoles, etc. Nevertheless, there will be a finite potential difference across the interface. However, because this potential difference across the interface is not due to any potential-determining ion, it cannot provide a useful analytical signal. An analytically useful signal can be obtained only if a charge-transfer process can occur which results in a nonzero charge on each phase across the interface. Charge transfer may be caused by or influenced by concentration gradients, potential gradients, temperature gradients and/or pressure gradients.

### Figure 7

Periodic table diagrams for commercially available inorganic ions.
It is usual to classify charge-transfer processes as either Faradaic or non-Faradaic. A Faradaic process involves an oxidation or a reduction reaction. This type of process will alter the nature of certain ions or molecules on both sides of the interface. It has been shown that this type of process is frequently the basis of chemical interference for some type of membranes, but it does not usually lead to a potential difference across an interface that can be related to the activity of a potential-determining ion. One exception is the homogeneous Cu(II) membrane ISE, which will be discussed later. Thus, the relevant charge-transfer processes are mostly non-Faradaic. Examples of non-Faradaic chemical or physical processes that can lead to charge transfer are ion adsorption/desorption, complex formation, ion diffusion, ion extraction, and ion exchange.

A complete description of a membrane system involves the determination of various concentrations and potentials in both space and time. This requires that a set of partial differential equations for pertinent fluxes and a set of conservation equations be solved for some set of initial and boundary conditions. For the most general solution, only those initial and boundary conditions necessary to prevent the violation of physical laws may be specified. No such solution exists. Instead, solutions have been obtained for a number of special cases. In all of these special cases, temperature is kept constant.

We cannot examine all of these special cases here. Instead, it is instructive to examine the thermodynamic treatment for a number of simple cases in which the material properties of the nonaqueous phase are different. In every case, we consider that the aqueous phase and the nonaqueous phase have at least a univalent cation in common. Using in part the notation of Koryta, we consider first the interface for zero current flow in

\[
\alpha \quad P^+X^- \quad \beta \quad P^+e^- \quad (14)
\]

where \(\alpha\) is an aqueous solution of the strong electrolyte \(P^+X^-\) and \(\beta\) is a free electron metal \(P\) with ion cores \(P^+\) and free electrons \(e^-\). An example would be silver metal in contact with \(\text{AgNO}_3\). Since \(X^-\) is not potential determining, on the \(\alpha\) side of the interface, we have (Equation 15):

\[
\bar{\mu}_P = \bar{\mu}_{P^+}(\beta) + \mu_{e^-}(\beta) = \mu_P
\]

Substituting and rearranging gives Equation (18):

\[
(\bar{\mu}_P - \phi_\alpha) = \mu_{P^+}(\alpha) + \bar{\mu}_{e^-}(\beta) - \mu_P
\]

The chemical potentials may be written in terms of the standard chemical potential and the activity. For example (Equation 19):

\[
\mu_{P^+}(\alpha) = \mu_{P^+}^0(\alpha) + RT\ln[\text{aq}_{P^+}(\alpha)]
\]

Making this substitution, and given that \(\bar{a}_{e^-}(\beta) = a_P = 1\), we obtain Equation (20):

\[
\phi_\beta - \phi_\alpha = K + RT\ln[\text{aq}_{P^+}(\alpha)]
\]

where \(K\) is given by

\[
K = \left[ \frac{\mu_{P^+}^0(\alpha) + \bar{\mu}_{e^-}(\beta) - \mu_P^0}{\mu_P^0(\alpha)} \right]
\]

Next, consider the case in Equation (22):

\[
\alpha \quad P^+X^- \quad \beta \quad P^+X^- \quad (22)
\]

where \(\alpha\) is an aqueous phase containing the electrolyte \(P^+X^-\) and \(\beta\) is an immiscible, nonaqueous phase containing the same electrolyte. At equilibrium, we have (Equation 23):

\[
(\phi_\beta - \phi_\alpha) = [\mu_{P^+}(\alpha) - \mu_{P^+}(\beta)] - [\mu_{X^-}(\alpha) - \mu_{X^-}(\beta)]
\]

If there is differential transport of \(P^+\) and \(X^-\), then a Galvani potential difference results, but both ions are potential determining. How do we obtain an interface in which a single ion is potential determining? The result for
the aqueous solution/metal phase gives the clue. We see that \( X^- \) cannot cross into the metal side of the interface. Likewise, electrons cannot move from the metal into the solution phase. Therefore, if the negative ions in \( \alpha \) are excluded from \( \beta \), and the negative ions in \( \beta \) are excluded from \( \alpha \), only the cations will determine the Galvani potential difference. This would correspond to the case in Equation (24):

\[
\begin{align*}
\alpha & \quad \beta \\
P^+X^- & \quad P^+Y^-
\end{align*}
\]  

where \( X^- \) is hydrophilic and \( Y^- \) is lipophilic. This case represents the simplest model for the polymeric membrane-type ISEs. With the anion exclusions, Equation (23) becomes Equation (25):

\[
\phi_\beta - \phi_\alpha = [\mu_{P^+}(\alpha) - \mu_{P^+}(\beta)]
\]

\[
(\phi_\beta - \phi_\alpha) = \mu_{P^+}(\alpha) - \mu_{P^+}(\beta) + RT \ln \frac{a_{P^+}(\alpha)}{a_{P^+}(\beta)}
\]

If \( a_{P^+}(\beta) \) is constant, an equation similar in form to Equation (20) is obtained, with \( K \) given by Equation (27):

\[
K = \frac{\mu_{P^+}(\alpha) - \mu_{P^+}(\beta) + RT \ln [a_{P^+}(\beta)]}{[\mu_{P^+}(\alpha) - \mu_{P^+}(\beta)]}
\]

Notice that the interface in Equation (24) could just as easily represent an aqueous phase containing the electrolyte \( P^+X^- \) in contact with a sparingly soluble salt \( P^+Y^- \). Clearly, at equilibrium there will be some \( Y^- \) in \( \alpha \), but owing to the common ion effect, its activity will be very small over some range of activities for \( P^+ \). The interface can be approximated as one in which \( Y^- \) is essentially confined to \( \beta \), and the equation for the Galvani potential difference across the interface has the same form as Equation (25). Again, Equation (20) gives the final form of the mathematical expression for the Galvani potential difference. Equation (20) is a form of the Nernst equation for an interface at equilibrium. The Galvani potential difference across an interface cannot be measured. What can be measured is the potential difference across a cell. By coupling the indicator electrode to a reference electrode, we obtain an electrochemical cell whose potential difference is the sum of the potential differences across many interfaces. If all interfaces except for the interface between the external membrane surface and the sample solution are constant, then \( E_{cell} = (\phi_\beta - \phi_\alpha) + K' \). Furthermore, if we write \( E_{cell} = E_{ind} - E_{ref} \), the potential difference between the indicator electrode (metal or ISE in the cases above) and the reference electrode, then the electrode potential for the indicator may be written in its usual form (Equation 28):

\[
E_{ind} = K_{electrode} + \frac{RT}{z} \ln [a_{P^+}(\alpha)]
\]

where any liquid junction potentials in the cell are assumed to be negligible. Converting to common logarithms and generalizing to a potential-determining ion with charge \( z \), sign and magnitude, Equation (28) becomes Equation (29):

\[
E_{ind} = K_{electrode} + \frac{2.303RT}{z} \log [a_Q]
\]

where \( Q \) is the target ion shown in Figure 8. At 25°C, the magnitude of the multiplicand of the logarithm terms is 59.2, 29.6, and 19.7 mV for \( z = \pm 1, \pm 2, \) and \( \pm 3 \), respectively. In practice, these ideal values are frequently not observed for ISEs, so it is common practice to add a so-called efficiency factor, \( \beta \), to that term and to treat the multiplicand as a constant which must be measured. Thus, most textbooks give Equation (30) for the electrode response of an ISE:

\[
E_{ISE} = E_{electrode} + \beta \frac{2.303RT}{z} \log [a_Q]
\]

If \( Q \) can be transported through the membrane, i.e. the membrane is an ionic conductor for \( Q \), then there may be a membrane diffusion potential difference across the bulk membrane. Frequently, it is the case that the ion transported through the membrane is not the potential-determining ion responsible for the potentials generated at the boundaries. Even in that case, a membrane diffusion potential difference across the bulk membrane may be generated. The transport equations have been solved for several applicable cases. The mathematical formulation is at best quasi-thermodynamic. Fortunately, it has been shown that the diffusion potential difference across the bulk membrane is negligible for most practical cases.

The time-variable properties of ISEs determine the upper limit to the rate of sampling. They are particularly important in flow analysis applications or in monitoring fast processes. These properties are determined by subjecting an ISE to activity steps. The time-variable properties of ISEs are referred to as their dynamic characteristics. In Figure 9(a) and (b) are shown the responses of a Corning \( 1^-/CN^- \) ISE to forward and reverse iodide steps.

The characterization of the dynamic response behavior of ISEs seems to have commenced in the mid-1960s, but progress has been slow owing to the complexity of the membrane response mechanisms. The figure of merit for the dynamic characteristics of an ISE is the response time. This has variously been defined in the literature as \( t_{1/2}, t_{90}, t_{95}, \) or \( t_{99.5} \) (times to reach 50%, 90%, 95%, or 99.5% of the total potential change) for a 10-fold activity change. The IUPAC recommendation
for the definition of this parameter is the following: “The time which elapses between the instant when an ISE and a reference electrode (ISE cell) are brought into contact with a sample solution (or at which the activity of the ion of interest in a solution is changed) and the first instance at which the electromotive force (emf)/time slope \((\Delta E/\Delta t)\) becomes equal to a limiting value selected on the basis of the experimental conditions and/or requirements concerning the accuracy (e.g. 0.6 mV min\(^{-1}\))... In clinical applications (the physiological activity range corresponds to a small emf span), a smaller slope, e.g. 0.1 mV min\(^{-1}\), may be chosen, provided the standard deviation of the response is less than the required slope.”\(^{(1)}\) The response time defined as the time from which the activity step is initiated until the slope becomes zero is identical to \(t_{100}\).

Both of these definitions are impractical, because many electrodes never reach a constant potential after the step. Unfortunately, it is not usually possible to convert from one definition to another, because the mathematical equation for the potential as a function of time must be known. There does not seem to be a single equation that adequately represents the time response for all ISEs. Berube et al.\(^{(78)}\) examined eight different models from the literature for a study on the homogeneous, crystalline iodide ISE. If the measured time response is not corrected for drift, the determined response time will not be accurate. Drift is defined as “the slow non-random change with time in the emf of an ion-selective electrode cell assembly maintained in a solution of constant composition and temperature”\(^{(1)}\). The drift may be measured on the front end before the activity step, and we have no choice but to assume that it does not change as a result of the step. If precise response times need to be known, then independent studies on drift as a function of the activity of the potential-determining ion should be performed. It is necessary to define the initial and final solution conditions for the step, since the response curves depend on these.

Finally, this subsection concludes with a discussion of the general treatment of electrode interferences. The 1994 IUPAC recommendations specify that the general expression for electrode response is the modified Nikolsky–Eisenman equation, given by Equation (31):\(^{(1)}\)

\[
E_{\text{ISE}} = K_{\text{electrode}} + \frac{2.303RT}{z \log a_A + \sum K_{\text{pot}}^{\text{A,B}} (a_B)^z} \tag{31}
\]

where \(K_{\text{pot}}^{\text{A,B}}\) are selectivity coefficients.

Over the years, several different methods have been proposed for the evaluation of selectivity coefficients. The IUPAC recommendation is that the fixed interference method is preferred and the separate solution method is acceptable, but less desirable. When the analyte ion and the electrode interferences have the same charge (sign and magnitude), and when the response is Nernstian for solutions of each type of ion, then the electrode interference is adequately described by the Nikolsky–Eisenman formalism. This formalism fails when either of these conditions is not met. Bakker et al.\(^{(79)}\) examined critically the Nikolsky–Eisenman formalism for polymer membrane-based ISEs, demonstrated its general inadequacy and proposed a new formalism, which they showed corresponded to the matched potential method proposed earlier by Gadzekpo and Christian.\(^{(80)}\) Umezawa et al.\(^{(81)}\) critically evaluated the validity of Equation (28) for two crystalline membrane ISEs and three liquid membrane ISEs. They also recommended that selectivity coefficients be obtained using the matched potential method. More recently, Nägele et al.\(^{(82)}\) developed a general formalism for electrode interferences for polymer membrane-based ISEs. Thus, the formalism for the response of polymeric membrane ISEs in the presence of electrode interferences has been completely and rigorously established. Since it is based on ion extraction/exchange equilibria, the formalism is not necessarily a general one applicable
to all ISEs. These results will be discussed in more detail under the specific heading of noncrystalline electrodes.

By using statistical mechanics and equations obtained from nonequilibrium thermodynamics, Hall\(^{[83]}\) developed a general limiting expression valid for electrode interferences whose charges differ in both sign and magnitude. In this treatment, the total potential difference across the membrane is not partitioned into phase boundary potentials and a diffusion potential. With reference to Figure 8(a), Hall writes the potential difference across the membrane as \(\phi^{(1)} - \phi^{(2)}\), which can be written as Equation (32):

\[
\phi^{(1)} - \phi^{(2)} = \frac{\bar{\mu}^{(1)}_Q - \bar{\mu}^{(2)}_Q}{z} - \frac{\mu^{(1)}_Q - \mu^{(2)}_Q}{z}
\]

where \(z\) is the charge on \(Q\). The first term in Equation (32) is the deviation of the membrane response from Nernstian behavior; it represents the contribution to the cell emf due to interference. In the equilibrium thermodynamic treatment, this term is zero. Considering both ionic and nonionic interferences, Hall developed a general expression for the interference term. Unfortunately, from a practical perspective, the mathematical expression is not useful. If it were possible to correlate these results with those obtained for the polymeric membranes, then it might be that modifications of those equations could be used for ISEs with other types of membranes.

### 3.2 Specific

The electrical properties of these membranes determine to a great extent the nature of their response to potential-determining ions. Both the electronic properties and the electrolytic properties must be considered. It is common knowledge that electronic materials may be classified as conductors, semiconductors, or insulators, based on the magnitude of their conductivities. It is not as widely appreciated that a similar classification scheme exists for electrolytic materials. They may be fast-ion conductors, electrolytic semiconductors, or electrolytic insulators. The boundaries between classes are determined by the magnitude of their ionic conductivities. In Table 1, we show these two classification schemes.\(^{[84]}\)

**Figure 10** The segmented membrane model for (a) primary ISE and (b) a metal contact or all-solid-state ISE. In the latter case, the space-charge region in the membrane at the membrane/electronic conductor interface is not shown.

#### 3.2.1 Primary Ion-selective Electrodes

**3.2.1.1 Crystalline Electrodes** The active materials in these electrodes are sparingly soluble, inorganic salts. They vary widely in their properties. Commercial electrodes with membranes in this category are the fluoride, chloride, bromide, iodide, sulfide, cyanide, thiocyanate, cadmium ion, cupric ion, lead ion, silver ion and mercuric ion ISEs. The fluoride ISE is the most important member of this group. Direct potentiometry for the in vitro determination of fluoride is the method of choice. Official methods for the determination of fluoride by use of the fluoride ISE appear in the *Official Methods of Analysis* Manual of the Association of Official Analytical Chemists, and also manuals of analysis published by the American Society for Testing and Materials and the Environmental Protection Agency. The active material of the fluoride ISE is lanthanum fluoride, a wide band gap electronic insulator, but an electrolytic semiconductor. Fluoride ion is the mobile charge carrier in this defect ionic conductor. Impedance spectroscopy\(^{[85]}\) and X-ray photoelectron spectroscopy (XPS)\(^{[86]}\) show that it forms a surface-hydrolyzed layer on contact with solution, hence a better model for this ISE is the segmented membrane model shown in Figure 10(a) and (b).

The solution in contact with the membrane may also be regarded as segmented into a bulk solution and a stagnant
layer in contact with the electrode. In a stirred solution, there is convection in the bulk, but no convection in the stagnant layer. Although a gel layer has been considered critical for the response of glass membrane electrodes, or the fluoride ISE, the gel layer may not be essential for the response, and is sometimes actually detrimental. The gel layer, described as LaF$_3$·3H$_2$O, is produced by diffusion of water into the membrane; it reaches a thickness of 20 nm in less than 1 week. The dynamic response of the electrode is not significantly affected by the gel layer, but with increasing time, leaching of fluoride is observed, concomitant with the incorporation of hydroxide. The aged electrode shows a sluggish response to a decade fluoride activity step and the change in emf becomes significantly less than Nernstian. After 18 weeks of aging, the first 5 nm of the 20-nm-thick gel layer has the stoichiometry LaF$_3$·n(OH)$_n$·mH$_2$O. Fortunately, the aging effects may be reversed by polishing. At room temperature, hydroxide is the only electrode interferent; the mechanism of interference has been shown to be ion exchange in the gel layer.$^{(87)}$ A very significant result of that study is that carbonate and phosphate, both of which form sparingly soluble salts with lanthanum, adsorbed on the membrane but did not affect the potential response at 20 °C, but at 60 °C the two ions did interfere with the potential response. At that temperature, they undergo ion exchange in the gel layer. There is some debate as to whether adsorption/desorption or ion exchange is the mechanism for potential generation of crystalline membrane ISEs. Experiments such as these may allow the debate to be resolved. The lanthanum fluoride membrane has not been used for the direct determination of lanthanum, so the membrane apparently does not give a useful potential response to this ion. The useful concentration range is from saturated to 10$^{-6}$ M fluoride.

The other commercial crystalline membrane ISEs are based on sparingly soluble silver salts or a homogeneous mixture of silver sulfide and a sparingly soluble metal sulfide. The silver salts are mixed conductors, so that chemical interference from redox active species, in addition to electrode interferences, may adversely affect an analysis. For example, a chloride ISE may have silver chloride as its active material. Silver chloride is a mixed conductor; it is an electronic semiconductor and an electrolytic semiconductor (silver ion is the mobile ion). Redox interference is determined by the electronic band gap of the material. The band gap of the silver salts is large enough that redox interference is not usually a problem in practice.

The silver chloride membrane ISE differs from the fluoride ISE in other ways: the electrode does not have a gel layer and it gives a Nernstian response to both silver ions and chloride ions. An example of the response behavior is shown in Figure 11.

Note that the electrode gives a constant response whenever the activity of chloride or the activity of silver ion is less than the square root of the $K_{sp}$ of silver chloride. By calling chloride ion a silver ion buffer and drawing the collinear line segments as a single straight line, the linear dynamic range for silver activity has been said to extend from 0.10 to 1.0 × 10$^{-6}$ M. Mechanistically, these curves indicate that when silver ion is the dominant ion in solution, its interaction with the membrane determines the potential, and vice versa for chloride ion. It is well known that when solid silver chloride is present in a solution with excess silver ion (cation common ion effect), silver ion adsors on the surface of the solid. When the solid is in a solution with excess chloride ion (anion common ion effect), chloride ion adsors on the solid.

Adsorption/desorption equilibrium at a membrane–electrolyte interface will alter the distribution of defects in the space-charge layer of the membrane. For example, it has been shown that the space-charge potential of a silver chloride membrane in contact with an aqueous solution containing silver ion depends on pAg. $^{(88,89)}$ A diffusion-controlled transport model with $D \approx 5 \times 10^{-8}$ cm$^2$ s$^{-1}$ gave a good fit to experimental conductance and capacitance data obtained on a frequency range of 30–10$^5$ Hz. Using data from Hoyen et al., $^{(89)}$ the thickness of the space-charge layer is calculated to be 25 nm. An estimate of the time constant needed to achieve a new equilibrium in the space-charge region after changing the activity of silver ion or chloride ion at the membrane surface is given by Equation (33):

$$\tau = \frac{4\delta}{\pi^2 D}$$

(33)
for first-order diffusion transport, where \( \delta \) is the space-charge layer thickness. A value of 64\( \mu \)s is obtained, which corresponds to a \( f_{95} \) response time of 192\( \mu \)s (\( f_{95} = 3\tau \)). Rangarajan and Rechnitz\((96)\) found \( f_{95} \approx 200 \) ms for an Orion-type 94-17-00 electrode subjected to a 10-fold concentration step-up in an electrode flow chamber. Pungor\((91)\) reported a response time of 20 ms, which is probably \( \tau \), using a switched wall-jet measuring cell arrangement. The experimental response times include diffusion across the Nernst layer plus whatever process gives rise to the interfacial potential. Adsorption/desorption leading to modulation of the space-charge defect distribution in the space-charge layer is fast enough to account for these experimental results.

Buck\((84)\) found that the impedance plots for silver chloride were independent of pCl. This would seem to suggest that chloride adsorption did not modulate the space-charge distribution, so that adsorption alone must be responsible for the interfacial potential at the membrane. In essence, the potential is changed only at the top monolayer of the membrane, which is equivalent to causing a jump discontinuity in the space-charge potential distribution. This is consistent with the coupled diffusion/adsorption model used by Berube et al.\((78)\) to interpret dynamic response data for the iodide ISE perturbed by iodide steps. Here, diffusion refers to the transport that occurs through the Nernst layer. The bromide ISE based on silver bromide is in all respects similar to the chloride and iodide ISEs.

Silver sulfide has a much smaller band gap than the silver halides. At room temperature, the most stable crystallographic form is \( \beta \)-Ag\(_2\)S, which has a silver ion conductivity of 3.60 \( \times \) 10\(^{-4}\) \( \Omega^{-1} \) cm\(^{-1}\) and an electronic conductivity of only 4.00 \( \times \) 10\(^{-6}\) \( \Omega^{-1} \) cm\(^{-1}\). Hence, its electrolytic properties dominate, and it is this form that is useful as an ion sensor. Not only is it a sensor for silver ions and sulfide ions, but it is also a component of the homogeneous mixture membranes of the cadmium ISE (CdS/Ag\(_2\)S), the lead ISE (PbS/Ag\(_2\)S), the copper ISE (Cu\(_2\)S/Ag\(_2\)S and CuS/Ag\(_2\)S), the mercury(II) ISE (HgS/Ag\(_2\)S), and the iodide/cyanide ISE (AgI/Ag\(_2\)S). Other metal sulfide/silver sulfide homogeneous mixture membranes have been studied, but they have not been commercialized.

Like lanthanum fluoride, the surface of silver sulfide becomes hydrated on soaking in water.\(^{(92)}\) However, the concentration profile for water shows an approximate exponential decay, \( e^{-\lambda d} \), with depth \( d \) into the membrane. The reciprocal of \( \lambda \) is \( \approx \)2 nm, and at \( d \approx \)8 nm, the boundary with dry silver sulfide is reached. The interfacial potential is believed to be generated by a space-charge mechanism.\(^{(92)}\) The divalent sulfides are electronic semiconductors but electrolytic insulators. In the homogeneous mixtures, they provide absorption centers for the divalent cations, while the silver sulfide provides the electrolytic conductivity. However, in an elegant experiment, Uosaki et al.\(^{(93)}\) showed that a single crystal of CdS functions as an ISE. The configuration was one of all solid state, and the external surface was either an (0001) Cd face or an (0001) S face. The (0001) Cd face showed a Nernstian response to HS\(^-\) concentration (Na\(_2\)S solutions buffered at pH 9) and the (0001) S face showed a Nernstian response to Cd\(^{2+}\) concentration. The results have been plotted in Figure 12 using the same format as Figure 11.

The equilibrium expression allowing the concentrations of Cd\(^{2+}\) and HS\(^-\) to be related is given by Equation (34):

\[
\text{CdS(s)} + \text{H}_2\text{O} \rightleftharpoons \text{Cd}^{2+} + \text{HS}^- + \text{OH}^- \tag{34}
\]

with \( K = 6.4 \times 10^{-28} \). Since \( p\text{H} = 9.0 \), \( C_{\text{Cd}} \times C_{\text{HS}} = 6.4 \times 10^{-19} \), where activity effects have been ignored. The plot is analogous to those obtained for silver iodide and silver sulfide.\(^{(94)}\) Most significantly, the slopes of the emf versus log \( C \) plots were identical with the slopes of the flat band potential versus log \( C \). This is, perhaps, the strongest evidence yet for an adsorption mechanism for interfacial potential generation. As discussed in that paper, a general equation for the variation of the flat band potential with activity of the adsorbate, assuming a Frumkin adsorption isotherm, reduces to the Nernst equation when there are a large number of adsorption sites and there is no interaction between adsorbates. Because repulsion will

![Figure 12](image-url)

**Figure 12** Response of a single-crystal cadmium sulfide ISE to solutions of cadmium ions and solutions of hydrogen sulfide ions. (○) Point of intersection of the extended linear regions; (•) point on extended hydrogen sulfide line where the hydrogen sulfide concentration equals 8 \( \times \) 10\(^{-18}\) M; (●) point on extended cadmium line where the cadmium concentration equals 8 \( \times \) 10\(^{-19}\) M.
keep adsorbates from approaching close to each other on the surface, this approximation will almost always be valid.

The electrode interferences for these ISEs are easy to predict. Any cation or anion which forms a sparingly soluble salt with the counterion of the membrane is an electrode interference. A metathetical reaction, which alters the membrane surface composition and modifies the electrode response, will occur. The selectivity order may be predicted by calculating the equilibrium constant of the metathetical reaction using pertinent activity product constants. Selectivity will be of the order of the \( K \) values: the larger is \( K \), the more serious is the interference by the ion. For quantitative work the selectivity coefficients should be measured.

These electrodes are also subject to numerous chemical interferences. The lead, cadmium and copper ISEs are subject to oxidation or reduction by sufficiently strong redox-active species. If the band gap is small, then photodegradation may also occur. Photodegradation may activate oxidation or reduction reactions which are energetically unfavorable in the absence of light. It can also catalyze the degradation of chemical interferences. All of the cations in these membranes form complex ions with some ligands. These are usually charged species, and therefore have a high solubility in aqueous media. The net result is that etching or leaching of the membrane will occur. Mild etching will cause so-called sub-Nernstian responses and longer response times. Severe etching may cause loss of response. In many cases, the responses of the electrodes may be restored by mechanical polishing. However, since membrane material is lost with each polish, the lifetime of the electrode will be significantly diminished. It is best to avoid exposing the electrodes to solutions containing known interferences. The interference problem has somewhat limited the use of these electrodes as detectors for real-time analysis of complex samples by methods such as flow injection analysis. Taken as a set, the quantitation detection limits of these electrodes range from \( 10^{-8} \) to \( 5 \times 10^{-5} \) M, with \( 6 \times 10^{-6} \) M as the median value. The upper quantitation detection limits range from \( 10^{-2} \) M to saturation, with \( 1.0 \) M as the median value.

3.2.1.2 Noncrystalline Electrodes The glass membrane electrodes and the electrodes with mobile charged sites, the various ionophore-containing polymer membranes, belong to this class. There are many types of inorganic glasses, but the silicate glasses are the only ones used to make commercial ion-sensing membranes. The most important ISEs of this type are the pH electrode and the sodium ion electrode. Silicate glass is formed from \( \text{SiO}_2 \), a network former, and one or more metal oxides, network modifiers. For example, in a sodium silicate glass, some of the oxygen atoms are bonded to two silicon atoms (bridging oxygen), other oxygen atoms are bonded to only one silicon atom [nonbridging oxygen (NBO) atoms], which carry a charge of \(-1\), and sodium ions are either electrostatically bonded to NBOs or isolated in percolation channels. Percolation channels are tunnels through which alkali metal ions may move. Some network modifiers, e.g. aluminum oxide, give rise to substitutional impurities in the network itself, e.g. an aluminum substitute for a silicon. When the valence of the substitutional impurity is not the same as that of silicon, a second network modifier, an alkali or alkaline earth metal oxide, must be used to provide for charge compensation.

Although silica glass membrane electrodes have been studied since the beginning of this century, it is easy to understand why their behavior is still being characterized. The properties of these materials are not monolithic; they depend strongly on the chemical composition of the dry glass, on the history of its preparation, and on its state of hydration during utilization. Depending on its composition, a dry silicate glass can be an electronic insulator and an electrolytic semiconductor or an electronic insulator and an electrolytic insulator. For example, at \( 27^\circ\text{C} \) NAS 25-25 glass has a conductivity of \( 1.0 \times 10^{-8} \Omega^{-1} \text{cm}^{-1} \) and is an electrolytic semiconductor, while Corning 015 glass has a conductivity of \( 8.6 \times 10^{-12} \Omega^{-1} \text{cm}^{-1} \) and is an electrolytic insulator. The former types might be expected to exhibit some of the behavior that we have observed for crystalline membrane ISEs. In the dry state, the latter types can only behave as capacitative devices. However, sufficient hydration of a dry glass can cause it to undergo a transition from an electrolytic insulator to an electrolytic semiconductor. Thus, conflicting reports on the behavior of glasses with the same nominal chemical composition can probably be traced to a failure to consider their preparation and utilization histories.

All glass membrane ISEs respond to monovalent cations and \( \text{NH}_4^+ \), and to a lesser extent to divalent cations. The dry glass chemical composition determines which ion gives the greatest response, i.e. it defines the target, and also defines the selectivity order for electrode interferences.

In Table 2, some important glass compositions which are used as membranes to target \( \text{H}^+ \), \( \text{Na}^+ \) and \( \text{K}^+ \) are shown. Note that a gel layer forms on Corning 015 glass when it comes in contact with water or aqueous solutions. A glass scientist would say that Corning 015 glass is subject to “glass corrosion”. A glass subject to corrosion will begin to corrode immediately after water contact. As can be seen from Table 2, not all glasses are subject to significant glass corrosion.

Using infrared (IR) spectroscopy, Raman spectroscopy and magic-angle spinning (MAS) nuclear magnetic resonance (NMR) spectroscopy, Pandya et al.\textsuperscript{(95)} examined...
water at 5, 46, and 57°C. Water and for electrolyte solutions and for temperatures been characterized for Corning 015 glass, both for pure and potassium-containing glasses. A gel layer formed on the undensified glass. Similar behavior researchers showed a scanning electron micrograph of the membrane electrodes. The results on the lithia glass may exhibit a space-charge layer, and the mechanism of electrolytic semiconductivity. These glass electrodes will have no gel layer. In that case, the potential must be due to adsorption of hydronium ions or hydroxide ions limited to the surface layer. The adsorption model developed for CdS should apply. This is probably why pH electrodes based on lithia glasses have a quantitation concentration range from pH 0 to 14. The electrode probably has an upper quantitation detection limit of 1.0 M and a lower quantitation detection limit of 10⁻⁷ M for H⁺ and also for OH⁻. Hence the detection limits are similar to those observed for the crystalline membrane ISEs. For the sodium ISE, the upper quantitation detection limit is a saturated solution, and the lower quantitation detection limit is 10⁻⁶ M. More studies need to be carried out on these glasses, using techniques such as NMR, Raman spectroscopy, and scanning electron microscopy to characterize their behavior more fully.

The polymer-based liquid membrane ISEs come in three varieties: the neutral carrier-based ISE, the charged carrier-based ISE and the ion exchanger-based ISE. The ion exchanger-based ISE membrane has an ion exchanger dissolved in an organic solvent, and the resultant solution is dispersed in an inert polymer support. Traditionally, long-chain alkylammonium salts or nonlabile metal complexes have been considered to be anion exchangers. The electroactive carrier is dissolved in an organic solvent, and the organic solution formed is usually dispersed in an inert polymer support. For example, Nielsen et al. constructed a nitrate ISE from tetraethlammonium nitrate, dialkyl phthalate or dialkyl adipate, and PVC. When such a membrane is placed in contact with an aqueous phase, the tetraethlammonium ion is confined to the membrane, but the nitrate ion is free to move into or out of the membrane. An example of a nonlabile metal complex is Fe(II)(o-phen)₃(ClO₄)₂. The term nonlabile means that the Fe(II) ion is not present as the free ion in the membrane. The anion, which is the counter ion, is free to move. Cation exchangers are typically long-chain metal sulfonate salts or labile metal ion complexes dissolved in an organic solvent, with this organic solution dispersed in an inert polymeric support. For example, the first Ross calcium ISE membrane was formed from calcium bis(2-ethylhexyl phosphate) dissolved in dioctyl phenylphosphonate and supported in a

porous, inert polymer. The calcium bis(2-ethylhexyl phosphate) can ionize, and the free metal ion can move between the membrane and a contacting aqueous phase. However, the 2-ethylhexyl phosphate ligands, which carry a charge of $-1$, cannot leave the membrane.

Ion-exchanger ISE membranes are electronic insulators and electrolytic semiconductors. Potential generation for these membrane systems is similar to that for other electrolytic semiconductors. For example, Li and Harrison characterized a nitrite ion-selective membrane using spatial imaging photometry. The system consisted of bromo(pyridine)(5,10,15,20-tetraphenylporphinato) cobaltate in dioctyl adipate supported in PVC. They found that on exposure to water, hydration occurs, giving a gel layer that is about 50 $\mu$m thick. When the membrane was conditioned in a nitrite solution, the nitrite ion replaced the bromide ion. Nitrite ion diffused across the membrane, to give ultimately a nearly uniform distribution, but the diffusion coefficient was only about $5 \times 10^{-9} \text{ cm}^2 \text{ s}^{-1}$. The potential is established in a thin (~100 $\mu$m thick) region at the membrane/solution interface, i.e. a space-charge layer exists.

NMR studies have revealed that the uptake of water by polymer-based liquid membranes occurs in two stages. The first stage has been attributed to water miscibility in the membrane phase. This is equivalent to the existence of monomeric water in the silicate glasses. In the second stage, droplets of water are formed. With the charged-carrier ISE membrane, the carrier is charged in its uncomplexed state, and forms a neutral complex with the target ion. Such membranes also contain ion-exchanger sites, which are needed to insure permselectivity for the target ion.

An example of a charged-carrier anion ISE is the nitrite electrode based on the aquoacyanocobalt(III) heptakis(phenylethyl) cobyrinate ion. This membrane has the following composition: $1.0 \text{ wt\%}$ aquoacyanocobalt(III) heptakis(phenylethyl) cobyrinate perchlorate, $37 \text{ mol\%}$ potassium tetraakis[3,5-bis(trifluoromethyl) phenyl]borate (KTFPB), $65 \text{ wt\%}$ 2-nitrophenyl octyl ether (NPOE) and $33 \text{ wt\%}$ PVC. The ligand, confined to the membrane, carries a positive charge when not complexed to the target ion. Hence it excludes cations from the membrane. KTFPB is used to improve the selectivity of the membrane. It dissociates to give a large, lipophilic anion in the membrane which functions to exclude anions. Only an anion which forms a neutral complex with the carrier can enter the membrane.

A charged-carrier cation ISE will have the complementary membrane composition, i.e. a ligand which is negative when not complexed, a salt which contains a lipophilic cation, the solvent, and the polymer support. In their review, Bühllmann et al. included examples of attempts to form such electrodes, but it seems that none of them have given adequate responses or selectivity. For example, Midgley tried to make an ion-exchanger Fe(III) ISE based on the charged-carrier myobactin S. It failed to respond to Fe(III), but did respond to salicylate. The predominant mechanism responsible for potential generation for the charged-carrier ISEs is extraction by means of complex formation.

The third type of polymer-based liquid membrane is the neutral-carrier type. A neutral carrier is an uncharged, lipophilic complexing ligand. Some are large macrocycles with hydrophobic exteriors and internal cavities lined with polar groups. A metal ion which has a diameter such that a “lock and key” fit may occur between the metal and the ligand will form a strong complex with the ligand. Smaller or larger ions form weak or no complexes with the ligand. An example of a neutral-carrier macrocycle is shown in Figure 13(a). Many of the neutral carriers being used today are not macrocycles. Examples are the various Nile Blue oxazone derivatives (ETH $\text{wxyz}$, where $w$, $x$, $y$, and $z$ are integers) and para-substituted trifluorocarboxylic benzenes. The former are chromoionophores originally developed for optodes, but have now been used as neutral carriers for several different cations. The latter are neutral carriers used in commercial carbonate ISEs. An example of a neutral-carrier ISE membrane for a cation is the valinomycin potassium ion ISE. Valinomycin and potassium ion give a “lock and key” fit, as shown in Figure 13(b).

An example of a recipe for such a membrane is as follows: $1.0 \text{ wt\%}$ valinomycin, $0.01 \text{ wt\%}$ potassium tetrphenylborate ($\text{KBPh}_4$), $66.0 \text{ wt\%}$ dioctyl sebacate (DOS) and $33.0 \text{ wt\%}$ PVC. $\text{KBPh}_4$ is completely ionized in the organic solution, with the potassium ions all complexed by valinomycin and the tetrphenylborate ions constituting mobile negative ion sites confined to the membrane. A schematic of such a membrane is shown in Figure 14. The tetrphenylborate ions function to exclude sample anions from the membrane.

It has been shown that functional ISEs may be prepared without adding the ion-exchanger salt. Ye et al. showed by XPS and time-of-flight (TOF)
The membrane composition is as follows: trifluoroacetylbenzamide, a neutral carrier for carbonate.

An example of a neutral-carrier anion ISE is one whose membrane contains a neutral carrier for carbonate. The membrane composition is as follows: 3.4 wt% N,N-diocetyl-4-trifluorooctylbenzamide, 41 mol% tridodecylmethyleneammonium chloride (TDDMACI), 54 wt% DOS and 41 wt% PVC. Here, TDDMACI is the ion-exchanger salt, which gives large, lipophilic cations. These will be excluded from the membrane cations which do not complex with the neutral carrier. DOS is the solvent.

An example of a neutral-carrier anion ISE is one whose membrane contains N,N-diocetyl-4-trifluorooctylbenzamide, a neutral carrier for carbonate. The membrane composition is as follows: 3.4 wt% N,N-diocetyl-4-trifluorooctylbenzamide, 41 mol% tridodecylmethyleneammonium chloride (TDDMACI), 54 wt% DOS and 41 wt% PVC. Here, TDDMACI is the ion-exchanger salt, which gives large, lipophilic cations in the membrane. With the neutral carrier-type ISEs, the mechanism for potential generation is ion extraction. An excellent discussion of the potential generation mechanism for the valinomycin potassium electrode has been published by Sandifer, (108)

While the polymeric membrane ISEs are being used to analyze for lithium, potassium, magnesium and carbonate in commercial clinical analyzers, the greatest potential for these electrodes lies in their ability to be tailored for the analysis of biologically important organic cations and anions. The key is to find carriers that selectively target an analyte present at a low concentration in a complex sample with high concentrations of other ions. The ability to achieve selectivity by design has been greatly advanced by the recent development of a precise selectivity model for these electrodes. It began with a demonstration of the inability of the Nicolsky–Eisenman formalism to give self-consistent results for a target ion with charge +1 and an ion interference with charge +2. If we consider the electrode response for an ISE immersed in series of mixed solutions with a fixed activity of the ion interference of charge +2 in which the activity of the target ion of charge +1 varies, we expect the response to be described by a single curve which increases linearly as a function of the logarithm of the target activity. However, the Nicolsky–Eisenman formalism gives different curves, depending on whether the electrode is viewed as a sensor for Q or as a sensor for the ion interference. (79) By considering the response mechanisms for the three types of polymeric membrane electrodes and using appropriate electroneutrality conditions, complex formation constants and mass balances, the authors derived explicit electrode response functions for the case of zQ = +1 and zion interference = +2. This involved the introduction of a selectivity factor, ksel = the ratio of the activity of the target to the activity of the ion interference which gives the same potential when measurements are made in solutions of the single ions. For the ion-exchanger polymeric membrane, ksel can be expressed in terms of the so-called “single ion distribution coefficients”. For the charged-carrier polymeric membrane, ksel can be expressed in terms of respective single ion distribution coefficients and complex formation constants. For the neutral-carrier polymeric membrane, ksel depends on the total neutral carrier, as well as the single ion distribution coefficients and complex formation constants. The explicit functions are obtained by expressing the conventional Nicolsky selectivity coefficient in terms of ksel.

In a subsequent paper, (25) explicit response functions were given for the following coupled charge magnitudes: (1,2), (2,1), (1,3), (2,3), (3,2) and (3,1), where the first element of the pair corresponds to the target ion and the second to the ion interference. Most recently, a general implicit function valid for any number of sample ions with any type of charge has been developed. (82) Using $E_B$ as the phase boundary potential difference (this is directly proportional to $\phi_B - \phi_A$ in our treatment in the general section), the implicit function is given as
Equation (35): \( 1 = \sum_{i} a_{i} \text{org} K_{i} \exp \left( \frac{-z_{i}E_{B}}{s} \right) \) (35)

where \( i \) represents the ions, \( a \) is activity, \( z_{i} \) is the ion charge, \( s = RT/\lambda \) and \( K_{i} \) is a weighing factor, which combines a number of constants that depend on the type of polymeric membrane under consideration. For the ion-exchanger membrane, it is given by Equation (36): \( K_{i} = \frac{z_{i}k_{i}}{\gamma_{i}R_{T}} \) (36)

where \( k_{i} \) is the single ion distribution coefficient, \( \gamma_{i} \) is the activity coefficient and \( R_{T} \) is the concentration of nonexchangeable ions in the membrane. For the ionophore-based membrane (neutral carrier or charged carrier), \( K_{i} \) is given by Equation (37): \( K_{i} = \frac{z_{i}k_{i}^{0}c_{i}^{0} \text{org}^{n}}{R_{T}T_{i,n}} \) (37)

where \( \beta_{i,n} \) is the complex formation constant for ion \( i \) forming a 1:1 complex with the ligand, \( \gamma_{i,n} \) is the corresponding activity coefficient, \( c_{i}^{0} \text{org} \) is the initial concentration of the uncomplexed carrier, and the other terms have been defined above. Potentiometric selectivity coefficients are expressed in terms of these weighing factors as Equation (38): \( K_{i}^{\text{pot}} = K_{i}^{1/2z_{i}}/K_{i} \) (38)

In turn, \( k_{i}^{\text{sel}} \) can be related to the potentiometric selectivity coefficients, and this leads to a simple expression for the boundary potential (Equation 39): \( E = E_{i}^{0} + \frac{RT}{z_{i}} \ln a_{i}^{\text{aq}} + \sum_{j \neq i} k_{i,j}^{\text{sel}} a_{j}^{\text{aq}} \) (39)

The usefulness of the \( k_{i}^{\text{sel}} \) is obvious. First, by measuring single ion distribution coefficients and complex formation constants, and by determining the appropriate concentration of lipophilic ion sites needed, the selectivity of the membrane can be designed. Optimization techniques can be used to design membranes to give the best response for a set of specified ion interferences. This will allow the designer to generate quickly a set of membrane compositions likely to be suitable detectors for a given problem. The experimental work would then be limited to those compositions. Intelligent design allows time to be used more efficiently and minimizes waste of reagents.

Just as the interference order may be qualitatively predicted for crystalline membrane ISEs by using \( K_{\text{ap}} \) values, the selectivity order for charged-carrier ionophore anion ISEs often obeys the Hofmeister lyophilic series (Equation 40): \( R^{-} > \text{ClO}_{4}^{-} > \Gamma^{-} > \text{NO}_{3}^{-} > \text{Br}^{-} > \text{Cl}^{-} > \text{F}^{-} \) (40)

where \( R^{-} \) is an organic anion. For charged-carrier ionophore cation ISEs, the Hofmeister series is [Equation 41]: \( R^{+} > \text{Cs}^{+} > \text{Rb}^{+} > \text{K}^{+} > \text{Na}^{+} > \text{Li}^{+} \) (41)

where \( R^{+} \) is an organic cation. There does not appear to be a recurring selectivity order for divalent cations, etc. For the neutral carrier-type liquid membranes, the size and shape of the ion cavity determine the selectivity order to a large extent. It is possible to use molecular modeling techniques to investigate selectivity orders for any given neutral carrier. Since the organic solvent also influences the selectivity order, these methods are a kind of zeroth-order approximation. Commercially available macroelectrode ISEs with plastic membranes have an average quantitation lower detection limit of about \( 4 \times 10^{-6} \) M and an average quantitation upper detection limit of about 1.0 M. With crystalline membrane ISEs, the selectivity is determined by the properties of the solid. By buffering the sample solution, the lowest quantitation detection limits may be realized, but there can be no further improvement. With the polymeric membrane ISEs, the composition of the membrane can be changed to improve the selectivity, which, when coupled with buffering, can push the lower quantitation detection limit down. One way to improve membrane selectivity is to find more selective ionophores. This is why so much research in this area involves synthesizing and evaluating new ionophores, not only for new target ions, but also for ions that already have polymeric membrane ISE sensors. For example, neutral-carrier polymeric membrane ISEs for calcium and lead with lower quantitation detection limits of \( 10^{-9} \) M have been described. In comparison with the commercial calcium polymeric membrane ISE, this represents an improvement by a factor of 500, and in comparison with the commercial crystalline membrane lead ISE, an improvement by a factor of 1000.

3.2.2 Compound or Multiple Membrane Ion-selective Electrodes

These include gas-sensing electrodes (called Severinghaus-type potentiometric detectors) and enzyme electrodes. A gas-sensing electrode probes the concentration (activity) of a dissolved gas in an external solution as the result of admission of the dissolved gas into a compartment containing a solution which can interact with the gas to form the target ion of the internal ISE.
The compartment and the external solution are separated by a microporous, semipermeable membrane, so the gas must diffuse across this membrane. If the gas of interest is in the vapor phase, then its solution concentration (activity) will be determined by its solubility equilibrium. The process that occurs in the compartment is kinetically fast, so the response time of the electrode will be determined by the kinetics of the diffusion process and the kinetics of the ISE response. The former is always much slower. The measurement should be taken under steady-state conditions. The concentration (activity) of the gas can be measured related to the activity of the target ion by means of a mathematical expression based on the multiple equilibria which occur. No general expression is possible, but an example might be instructive. Suppose that we choose to monitor the partial pressure of ammonia in a stack gas using an ammonia gas ISE. The ammonia gas electrode contains a pH glass electrode, a compartment which contains either 10^{-3} \text{M} \text{NH}_3\text{Cl} or 0.1 \text{M} \text{KNO}_3, and a 0.1-mm micropore Teflon® membrane.\textsuperscript{112} The electrochemical cell consists of the ammonia gas electrode, a reference electrode and an external solution in contact with the stack gas. The concentration of dissolved ammonia is related to the partial pressure of ammonia gas in the stack gas by means of Henry’s law, \( P_{\text{gas}} = k[NH_3]_{\text{aq}} \). Since a concentration gradient exists across the membrane, ammonia diffuses into the compartment. The concentration of dissolved ammonia in the compartment when ammonia diffuses across the membrane, ammonia diffuses into the compartment. Diffusion must occur until the concentration gradient is zero, so the concentration of dissolved ammonia in the compartment will be the same as that in the external solution at steady state. If the compartment contains 0.1 M KNO\(_3\), then base hydrolysis of the ammonia fixes the hydroxide ion activity, which fixes the hydrogen ion activity. The ISE’s electrode response is related to \( P_{\text{gas}} \) by Equation (42):

\[
E_{\text{ISE}} = K_{\text{electrode}} + S \log \sqrt{k_KK_a} - \frac{S}{2} \log (P_{\text{gas}})
\]  

(42)

where \( S \) is the slope factor for the pH electrode and the relationship \( K_b = K_w/K_a \) has been used. The electrode gives a linear response as long as the approximation \([\text{NH}_4^+] = [\text{OH}^-]\) is valid, which is so long as the hydrolysis of water can be neglected. If 10^{-3} \text{M} \text{NH}_3\text{Cl} is in the compartment, then a buffer is formed in the compartment when ammonia diffuses across the membrane. In that case, the ISE’s response is related to \( P_{\text{gas}} \) by Equation (43):

\[
E_{\text{ISE}} = K_{\text{electrode}} + S \log (10^{-3}k_K) - S \log (P_{\text{gas}})
\]  

(43)

The electrode response is linear so long as the equilibrium concentrations of ammonia and ammonium ion are given by their analytical concentrations. In both cases, ionic strength effects must be adequately addressed. With these electrodes, the recovery times may be long (many minutes), so care must be taken to avoid memory effects in successive measurements. Interferences arise from other gases which can diffuse across the membrane and either control the activity of the target ion or form an ion which is an electrode interference for the internal ISE. For example, for the ammonia gas electrode, volatile amines interfere, since they can diffuse across the Teflon® membrane and they are weak bases, like ammonia. The quantitation lower detection limits for the commercial macroelectrode ISEs for NO\(_x\) and ammonia are 4 \times 10^{-6} and 5 \times 10^{-7} \text{M}, respectively. For the commercial carbon dioxide macroelectrode ISE, the quantitation lower detection limit is only 10^{-4} \text{M}. The detection ranges for the NO\(_x\) and for the carbon dioxide macroelectrode ISEs are fairly small; the quantitation upper detection limits are 5 \times 10^{-3} and 10^{-2} \text{M}, respectively. By contrast, the ammonia macroelectrode ISE has a quantitation upper detection limit of 1.0 \text{M}. Recently, polymeric membrane-type ISEs have been used to assemble carbon dioxide and ammonia sensors that are analogs to the Severinghaus-type sensors. The carbon dioxide sensor uses a neutral-carrier hydrogen ion polymeric membrane,\textsuperscript{26,113} whereas the ammonia electrode uses a neutral-carrier ammonium ion polymeric membrane.\textsuperscript{26,114–116} The neutral-carrier ammonium ion polymeric membrane shows an improved quantitation lower detection limit of 25, relative to the macroelectrode ISE. A neutral-carrier polymeric membrane-based ISE has been developed for sulfur dioxide.\textsuperscript{26} At present, there is no commercial macroelectrode ISE for this gas. Oxygen sensors have also been described,\textsuperscript{26} but it is not clear that the response is due entirely to ion transport and not electron transfer. These electrodes may not be ISEs in the traditional sense.

An enzyme electrode has a gel layer containing an enzyme interposed between the indicator ISE membrane and an external solution. The enzyme catalyzes the conversion of a substrate to a set of products, one of which is a target of the ISE. Targets are frequently small molecules or ions, e.g. ammonia, carbon dioxide, hydronium ion, cyanide ion.\textsuperscript{50} The selectivity of these electrodes is governed by the specificity of the enzyme. Because enzymes are stereoselective, these ISEs come the closest to being electrodes that give an activity-dependent response for a single type of molecule or ion, the substrate of the enzyme. The generation of the signal requires three steps: (1) the substrate must diffuse from the external solution into the enzyme gel layer, (2) the enzyme must catalysis the conversion to the set of products and (3) the product which is the ISE target must diffuse to the surface of the ISE membrane. In principle, the kinetics associated with step 2 can be complex. Also, while the concentration gradient is such
that the substrate diffuses into the gel, the products will
diffuse both toward the membrane surface and toward
the external solution. Practitioners have chosen enzyme
systems which obey Michaelis–Menten kinetics, which
is the simplest type. Even so, the transport equations
are inherently nonlinear. In order to obtain an equation
which relates the potential of the enzyme electrode to
the substrate activity (concentration), the equations are
solved for steady-state conditions. At the steady state,
the diffusion processes may be ignored, and only step 2
is important. In such a case, a set of simultaneous
first-order differential equations need to be solved. An
example of such a treatment can be found in the book by
Morf. \(^{117}\) Brady and Carr \(^{118}\) actually solved numerically
the coupled set of nonlinear, second-order differential
equations for a set of reasonable boundary conditions.
Since an expression for the electrode potential as a
function of substrate activity (concentration) cannot be
obtained in analytical form, this method is not useful
to the practitioner. However, it has allowed certain
approximations, which constitute general guidelines for
the use of such electrodes, to be validated. In general,
a linear response region is observed, the lower bound
being determined by the ionic background in the sample,
and the upper bound being determined by the Michaelis
constant for the enzyme system.

3.2.3 Metal Contact or All-solid-state Electrodes

The behavior of these electrodes is similar to that of the
primary electrodes. One type of failure which we have
seen for microelectrodes of this type is the decoration
of the membrane surface with silver, when silver is used
to make the internal contact. Silver atoms have fairly
large diffusion constants, in comparison with other metal
atoms, and thus even microcracks will result in its ultimate
transport to the surface. When this happens, the electrode
response gives sub-Nernstian slope factors.

4 INSTRUMENTATION

An ISE measurement involves the determination of the
potential difference between an ISE and an external
reference electrode. The instrumentation used to make
this voltage measurement must not load the circuit.
There are two types of instrumentation that may be
used to make voltage measurements – a potentiometer
or a voltmeter. A potentiometer is a null device, whose
limitations depend on the current sensitivity of the null
detector. The classical voltmeter is a direct measuring
device, e.g. the D’Arsonval meter, in which a small current
causes a meter deflection. For a given electrochemical
cell, the absolute error in the voltage measurement will
depend on both the magnitude of the actual voltage to be
measured and on the meter resistance (impedance). The
electrochemical cell resistance is determined essentially
by the resistance of the ISE, which in turn depends
on the geometry of the sensing membrane. In Table 3
are shown some typical values of ISE resistances for
various types of electrodes. \(^{119,120}\) The meter resistance
needed to give an absolute error of no more than
1 mV for the measurement of pH values from 1 to 14
may be calculated using the extremes of the output
potential range, \(+414\) to \(–414\) mV. \(^{119}\) A value of
8.0 \(\times\) 10\(^{11}\) \(\Omega\) is calculated. Thus, a meter resistance
(impedance) of 10\(^3\) – 10\(^4\) times that of the cell resistance
is needed.

Classical voltmeters, so-called VOM instruments, cannot
be used to measure the voltages of electrochemical
cell using ISEs, because the meter resistances
(impedances) are too small (typically 1 \(\times\) 10\(^2\) \(\Omega\)). Thus,
early pH meters made use of potentiometers, wherein
the null detectors evolved from galvanometers to vac-
um tube configurations. However, the classical instru-
mamentation era culminated with the development of
the vacuum tube voltmeter by A. O. Beckman. This
interesting history has been discussed by Jaselskis
et al. \(^{121}\)

The semiconductor revolution introduced the next
innovation, as vacuum tubes were replaced by semicon-
ductors, giving rise to the electronic voltmeter. The early
electronic ion meters were meter readout instruments, but
today’s electronic ion meters are digital readout instru-
ments, which utilize either a light-emitting diode (LED)
display or a liquid crystal display (LCD). These instru-
mants can have meter resistances (impedances) in excess
of 10\(^13\) \(\Omega\). The heart of a modern electronic ion meter is the
operational amplifier. The operational amplifier is a small-
scale integration device which has a high input impedance
(\(\geq 10^{12}\) \(\Omega\)), a low output impedance (\(\leq 1\) – 10\(^2\) \(\Omega\)), and
a large open-loop gain (10\(^4\) – 10\(^6\)). \(^{122}\) Many circuit design
are possible; in Figure 15 is shown a simple circuit design
which uses a voltage follower configuration with manual
adjustment for the slope factor. Slope factor adjustment
is needed to adjust for measurements made at different
temperatures.

Modern digital instruments have many more features. Most are microprocessor control instruments with multiple measuring modes (e.g. millivolts, pX, concentration mode in various units), with temperature compensation probes, and connectors for interfacing the instrument with auxiliary instruments. In Figure 16 is shown a block diagram of the Fisher Accumet Model 750 selective ion analyzer. The important circuits are shown in blocks. For example, the temperature compensation may be done manually (by entering information into the system via the keyboard) or automatically by means of a probe. The instrument has an analog-to-digital converter, and the digital data are available in binary coded decimal at an external connector and in decimal form at an LED display. This meter is a desktop model, and the technology dates from about 1981.

The new benchtop Accumet research meters are microprocessor-based instruments with backlit LCD touchscreens, prompts and context-specific help screens. In both the pH mode and ion mode, they offer up to five points of calibration. There are also portable Accumet meters that offer the same calibration options, but these do not have the help screens.

In Figures 17–19 are shown examples of the most recent Orion technology. In Figure 17 is shown the Orion Model 710A ion meter, a basic benchtop ISE/pH meter. It also uses an LCD and a touchpad input module with a large number of functions. It covers a pX range of −2.000 to 19.999, but the resolution depends on the pX value. For example, with pX = 7.00, the resolution is two decimal places. The meter has auto-buffer recognition for five-point pH standardization. There are built-in buffer/temperature tables. By contrast, the older
technology, e.g. the Accumet Model 750 meter mentioned above, uses two-point calibration, with the data entered into the system manually. In Figure 18, the Orion Model 290A meter is shown. This is an advanced, portable pH/ISE meter which is not much larger than a pocket calculator. Portable instruments are ideal for field measurements; the two-way RS232 communication and datalogging capabilities allow results to be downloaded later into a laboratory computer. In Figure 19 is shown one of the Orion SensorLink® systems. This is a PCMCIA card-based system, shown here interfaced with a PC; systems are also available for laptop computers. A standard Windows interface, using either Windows 95 or Windows 3.1, is used. The laptop systems are ideal for traveling scientific consultants or for Environmental Protection Agency compliance officers. Data can be obtained and analyzed and reports generated all within 1 day. The portable pH/ISE meters and the card-based systems are truly the wave of the future, being realized today.

5 ION-SELECTIVE MICROELECTRODES

As we have seen, the development of the pH electrode was initiated by researchers interested in making physiological measurements of acidity. Although the Beckman pH meter revolutionized the routine measurement of pH in wine, pickling baths, etc., the first pH meter for measuring the pH of blood was not introduced until 1954. ISE technology has replaced many of the clinical analysis techniques based on colorimetric analysis, flame photometry, and atomic absorption. Flame photometry was once the method of choice for the determination of lithium, sodium and potassium in samples. However, the inorganic material had to be separated from its biological matrix, a time-consuming process. Using ISE analyzers, whole blood samples can be analyzed for these ions. Atomic absorption used to be the method of choice for...
the clinical determination of calcium and magnesium. ISE analyzers are now used for these determinations. The trend has been to replace multiple instruments with a single analyzer capable of providing analysis for multiple targets. For example, the Nova 16 Stat chemical analyzer, an all-electrode (but not all-ISE) instrument, provides for the analysis of blood urea nitrogen, glucose, creatinine, sodium, potassium, chloride, and total carbon dioxide in less than 1 mL of whole blood.

The development of ISEs for both in vivo and in vitro biological measurements and medical applications has always been a goal of researchers in the health-related fields and in the biological sciences. Since in vivo measurements must be made in very tiny compartments, very tiny probes – microelectrodes – have to be developed. Ammann \textsuperscript{124} presented an excellent chart of the size ranges of various biological compartments, against which we may assess how far we have come and how much further we need to go in developing such electrodes. In Table 4, that information is shown using the median size of the biological compartments. In Figure 20 the three most useful geometries, in our opinion, for making in vivo measurement are shown. Coated-wire electrodes can be inserted into egg cells, but they are too large to be inserted into any of the other cells. The catheter electrodes are about the same size as the coated-wire electrodes. Just as catheters are useful for the continuous injection of drugs intravenously, catheter electrodes could be used for the continuous monitoring of molecules and ions that circulate in the bloodstream. However, only the microelectrode has been made small enough that the contents of cells and some of their organelles may, in principle, be measured. The smallest tip diameter of an enzyme microelectrode is 2 µm, which means that these electrodes may be used to probe the cytoplasmic regions of plant and animal cells, vacuoles, and the nucleus. With the neutral carrier microelectrodes, with the smallest tip diameter of 300 nm, the above compartments, and also mitochondria, bacteria, and lysosomes, may be probed. For the ion-exchanger and charged-carrier-type polymeric membranes, microelectrodes with minimum tip diameters of 100 nm have been constructed. These can interrogate the same compartments as the neutral carrier-type microelectrodes, but are not small enough to insert into ribosomes or viruses.

The prospect of using enzyme microelectrodes for the in vivo, selective monitoring of biological molecules is extremely attractive. What is needed is another factor of 10 decrease in the smallest tip diameter of these microelectrodes. However, obtaining useful signals from these smaller microelectrodes would require concomitant improvements in instrumentation capabilities. At present, microelectrodes may have resistances of the order of 1 × 10\textsuperscript{12} Ω. A decrease in diameter by a factor of 10 with no decrease in thickness would cause the resistance to increase by a factor of 100. This means that for comparable measurement errors, the meter resistances also need to increase by the same factor. There are other problems. The resistance of the cable cladding needs to be much larger than the resistance of the ISE, so that voltage drops between the cable core and the cladding are negligible compared with the magnitude of the signal. When the cladding resistance and the ISE resistance are similar in magnitude, electrode cable shielding must be performed in such a way as to reduce the voltage drop between the cable core and the cable cladding to virtually zero.\textsuperscript{120} The cladding problem is already being encountered for ISE resistances of 1 × 10\textsuperscript{12} Ω. Commercially available neutral carrier microelectrodes exist for the monitoring of lithium, sodium, potassium, magnesium, calcium, and hydrogen ions. Since the uptake or release of various of these ions often accompanies metabolic processes, these are useful for in vivo studies. Numerous examples of intracellular measurements of ions using neutral carrier microelectrodes exist.\textsuperscript{123–129} Recently, a neutral-carrier polymeric ISE microelectrode was developed to study the uptake of cadmium in plant cells\textsuperscript{130}.

6 NOVEL DEVELOPMENTS IN ION-SELECTIVE ELECTRODE RESEARCH

In this section, some recent developments which show particular promise in advancing the field of ISEs are...
discussed. This section is not intended to be comprehensive, and may unintentionally reflect the biases of the author! The development of polymer membrane-type ISEs for clinical uses and for monitoring the condition of patients during surgical intervention or during their recuperation in critical care units is a very active area. Several specific reviews have appeared.\(^\text{131–133}\) In particular, the development of polymeric ISEs for polyion analysis must be mentioned. One such polyion is heparin. Heparin is a glycosaminoglycan that occurs naturally in mast cells and cells that line the walls of arteries. It functions as an anticoagulant, and is used in hemodialysis, during heart surgery, and postsurgically. A heparin ISE which slowly releases NO, a platelet antiaggregant agent, is scheduled to fly aboard the Mars Surveyor 2001 Lander.\(^\text{150}\) MECA (Mars Environmental Compatibility Assessment) contains a wet chemistry laboratory (WCL) that consists of four beakers, which contain sensor arrays that are mostly ISEs. Both solid-state and polymeric membrane electrodes are being used. In Table 5, the ISE sensors being used in the WCL are shown. Conspicuously absent are glass ISEs. Cracking due to thermal cycling and degradation of the insulation resistance led to catastrophic electrical leakage.

Of course, the monitor itself must not induce thrombosis, so it is important that the polymeric membrane be biocompatible. Therefore, studies on modified PVC and other polymer matrices have been carried out.\(^\text{137}\) A novel development is a heparin ISE which slowly releases NO, a platelet antiaggregant agent.\(^\text{138}\) A disadvantage of these ISEs is that heparin must be removed from the membrane between measurements. An improved cleaning method has recently been developed.\(^\text{139}\) The development of polyion-sensitive membrane ISEs for nonseparation immunoassays also seems promising.\(^\text{63}\) The ability to analyze economically and quickly undiluted blood samples for illicit drugs would be useful for sports compliance monitoring and also for police monitoring for drug use.

Another development is ion imaging by means of scanning ion-selective potentiometric microscopy.\(^\text{140}\) It was shown that this technique could be used to image ions over conducting and insulating targets. This comes very close to being a measuring instrument that does not perturb the system that is being measured. This instrument will make it possible to use microelectrodes in order to advance our understanding of the detailed behavior of macroelectrodes, which can be used as targets.

More developments in the area of simultaneous analyte monitoring are expected. This area began with the development of sensors for the simultaneous monitoring of two analytes, e.g. pH and carbon dioxide.\(^\text{141,142}\) The further development of ISE arrays for simultaneous multitarget determinations will continue.\(^\text{143,144}\) This also includes methods of microfabrication.\(^\text{145,146}\) The development of data acquisition cards, which allow as many as 14 different channels to be interfaced to a computer, and sampling under computer control make these types of arrays attractive. The main problem with ISE arrays is that many of the ion mixtures that one might want to determine give rise to a complex electrode interference problem. The development of data acquisition designs and chemometric approaches to the analysis of such data are steps toward solving that problem.\(^\text{147–149}\)

Finally, ISEs are heading to Mars! A project called MECA (Mars Environmental Compatibility Assessment) is scheduled to fly aboard the Mars Surveyor 2001 Lander.\(^\text{150}\) MECA contains a wet chemistry laboratory (WCL) that consists of four beakers, which contain sensor arrays that are mostly ISEs. Both solid-state and polymeric membrane electrodes are being used. In Table 5, the ISE sensors being used in the WCL are shown. Conspicuously absent are glass ISEs. Cracking due to thermal cycling and degradation of the insulation resistance led to catastrophic electrical leakage.

### LIST OF SYMBOLS

- \(a\): activity
- \(\beta\): efficiency factor in electrode potential equation
- \(\beta_{\text{L}}\): concentration, usually in mol L\(^{-1}\)
- \(c, C\): activity coefficient
- \(\delta\): space-charge layer thickness. SI units m, but usually expressed in \(\mu\)m, nm, etc.
- \(D\): diffusion coefficient. SI units m\(^2\) s\(^{-1}\), but frequently given in cm\(^2\) s\(^{-1}\) in the literature
- \(E\): cell emf, electrode emf, in V or mV; phase boundary potential difference
- \(\Gamma\): Faraday constant, 96,500 J C\(^{-1}\)
- \(k\): Henry’s constant
- \(k_i\): single ion distribution coefficient
- \(k^{\text{sel}}\): selectivity coefficient
- \(K\): constant in the Nernst equation in V or mV
- \(K_a\): acid dissociation constant
\[ K_b \] base hydrolysis constant
\[ K_i \] weighing factor
\[ K_{sp} \] solubility product constant
\[ K_w \] autoprotolysis constant of water
\[ K_{\text{Pot}}^{A,B} \] selectivity coefficient
\[ \mu \] chemical potential, \( \text{J mol}^{-1} \)
\[ p \] osmotic pressure
\[ P \] partial pressure of a gas, atm
\[ \Phi, \phi \] Galvani potential, V or mV
\[ R_T \] concentration of nonexchangeable ions
\[ S \] empirical slope factor, V or mV
\[ \tau \] time constant, s\(^{-1}\)
\[ t_0, t_c \] transport number
\[ X, \chi \] chi potential, V or mV

ION-SELECTIVE ELECTRODES: FUNDAMENTALS

30

This article outlines the electrochemical methodology at the interface between two electrolyte solutions (ITIES). The fundamental concepts of the thermodynamics in biphasic systems are presented in order to show how ions are distributed between the two adjacent phases, and hence how a Galvani potential difference is established at an ITIES. Polarizable and nonpolarizable ITIES are then characterized, and it is further evidenced that the classical electroanalytical methodology at a solid electrode can be directly transposed to the ITIES, thereby allowing reversible charge-transfer reactions to be easily monitored and interpreted.

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd
ionic motion in liquids,\(^1,^{146}\) and recent results suggest that the rate-limiting step in ion transport is the necessary interchange of the solvation shell from one liquid to the other. The roughness of the interface is likely to manifest itself as capillaries or fingers of one liquid protruding into another.\(^{47,48}\) This “fingering” resulting from the long-range ion–dipole interactions plays a major role in the change of the solvation shell,\(^{49}\) implying that ion transfer may be an activated process.\(^{50}\) This has been corroborated by molecular dynamics calculations\(^{49,51}\) which tend to confirm that the interface is not a sharp but an extended region in which the two solvents mix. One of the greatest challenges in the theory of ITIES is to understand the spatial distribution of the driving forces. From an electroanalytical viewpoint, the majority of the charge-transfer reactions studied are reversible (i.e. kinetically fast) and the development of their applications is not hindered by these theoretical limitations.

This article is intended to describe the general theory of charge-transfer reactions at ITIES and to outline the various methodologies that electrochemistry at liquid/liquid interfaces offers for analytical purposes. It does not deal with interfacial structure and kinetics, but focuses on the various applications of ITIES and on recent advances in this field. Also, the very important field of the ion-selective electrode (ISE),\(^{52–55}\) which is a significant application of electrochemistry at liquid/liquid interfaces is omitted, as it is a subject of its own.

2 THEORETICAL BACKGROUND

2.1 Thermodynamics for the Partition of Ions

2.1.1 Gibbs Energy of Transfer and Nernst Equation at the Interface Between Two Immiscible Electrolyte Solutions

The standard transfer Gibbs energy of a species from one phase (say water) to another phase (say the organic solvent), \(\Delta G_i^{o,w-o}\), is by definition equal to the difference between the standard Gibbs energy of solvation, \(\mu^{o,o}\), and the standard Gibbs energy of hydration, \(\mu^{o,w}\) (Equation 1):

\[
\Delta G_i^{o,w-o} = \mu^{o,o} - \mu^{o,w}
\]

In the case of an ionic species \(i\), we have to consider the electrochemical potentials which are equal at equilibrium. In developing this equality, we can write Equation (2):

\[
\mu_i^{o,w} + RT \ln a_i^w + z_i F \Phi^w = \mu_i^{o,o} + RT \ln a_i^o + z_i F \Phi^o
\]

from which we can express the Galvani potential difference between the two phases \(\Delta \phi^o\) according to Equation (3):

\[
\Delta \phi^o = \frac{\Delta \phi_i^o}{z_i F} + \frac{RT}{z_i F} \ln \left( \frac{a_i^o}{a_i^w} \right) = \Delta \phi_i^o + \frac{RT}{z_i F} \ln \left( \frac{c_i^o}{c_i^w} \right)
\]

where \(a_i^o\) and \(c_i^o\) are the activity and the concentration of the ion, respectively, in both phases and \(\Delta \phi_i^o\) and \(\Delta \phi_i^w\) are called the standard and the formal transfer potentials, respectively.

This equation is often called the Nernst equation for ion transfer at liquid/liquid interfaces, and the term \(\Delta \phi_i^w\) corresponds to the standard Gibbs energy of transfer expressed on a voltage scale (Equation 4):

\[
\Delta \phi_i^w = \frac{\Delta G_i^{o,w-o}}{z_i F}
\]

It is important to realize that although the Nernst equation for ion transfer resembles the classical Nernst equation for redox reactions on an electrode, there is no redox reaction involved in the definition of Equation (3).

If a ligand or an ionophore able to complex the transferring ion is present in the organic phase, then the complexation equilibrium can be taken into account. In the case of 1 : 1 stoichiometry, the association constant is simply given by Equation (5):

\[
K_a = \frac{a_{ML}^o}{a_{M}^o a_{L}^w}
\]

where \(M\) refers to the transferring ion and \(L\) to the ligand. The Galvani potential difference now reads as Equation (6):

\[
\Delta \phi^o = \Delta \phi_i^o + \frac{RT}{z_i M F} \ln \left( \frac{a_{ML}^o}{a_{M}^o a_{L}^w} \right)
\]

with the apparent standard transfer potential given by Equation (7):

\[
\Delta \phi_i^{o,ML} = \Delta \phi_i^w - \frac{RT}{z_i M F} \ln \left( K_a a_i^o \right)
\]

This equation shows that the presence of an ionophore in the organic phase can shift the apparent solvation energy and therefore facilitate the transfer of hydrophilic species from water to oil. We shall call this type of ion-transfer reaction facilitated ion transfer.

2.1.2 Polarizable and Non-polarizable Interface Between Two Immiscible Electrolyte Solutions

If a salt such as tetrabutylammonium bromide is dissolved in two immiscible solvents in contact, the distribution
of the salt induces a polarization of the interface. The resulting Galvani potential difference is then called a distribution potential and is defined by applying Equation (3) to both the cation and the anion (Equation 8):

$$\Delta_o^w \phi = \Delta_o^w \phi_o^c + \frac{RT}{F} \ln \left( \frac{a_o^c}{a_o^+} \right) = \Delta_o^w \phi_o^c - \frac{RT}{F} \ln \left( \frac{a_o^c}{a_o^-} \right)$$  \hspace{1cm} (8)

In the case of dilute solutions, this equation simplifies to Equation (9):

$$\Delta_o^w \phi = \frac{1}{2}(\Delta_o^w \phi_o^c + \Delta_o^w \phi_o^-)$$  \hspace{1cm} (9)

This simple example illustrates that as soon as we partition salts between two adjacent phases, the interface becomes polarized at a fixed potential defined by the standard transfer potentials of the different ionic species. Because this polarization potential is fixed, we shall say that the interface is nonpolarizable in the sense that it is not possible to polarize the interface without modifying the chemical composition of the two phases.

In the case where a hydrophilic salt is dissolved in water and a hydrophobic salt is dissolved in the organic phase such that the concentration of the hydrophilic salt in the organic phase is negligible compared with that of the hydrophobic salt and, conversely, the concentration of the hydrophobic salt in water is negligible compared with that of the hydrophilic salt, then the interface will be called polarizable. This definition means that it is now possible to polarize the interface from an external potential source without modifying the chemical composition of the adjacent phases. In this way, there is what is called a potential window such that it is possible to polarize the interface up to a point where the applied Galvani potential difference is enough for an ion to transfer.

To illustrate the principle of the potential window, let us consider an interface between an aqueous solution of Li₂SO₄ and a solution of tetrabutylammonium (TBA) tetraphenylborate (TPB⁻) in an organic solvent, e.g. 1,2-dichloroethane (1,2-DCE).

At the potential of zero charge, the two adjacent phases are by definition uncharged. If a positive Galvani potential difference (water vs oil) is applied from an external source, two back-to-back Gouy–Chapman diffuse layers will be established with an excess of cations in the aqueous phase and an excess of anions in the organic phase. As shown in Figure 1, we can polarize the interface until the Galvani potential difference reaches the standard transfer potential of either Li⁺ or TPB⁻. As it happens, the standard transfer potential of TPB⁻ is less than that of Li⁺ ($\Delta_o^w \phi_o^{TPB^-} = 340 \text{ mV}$ and $\Delta_o^w \phi_o^{Li^+} = 580 \text{ mV}$), and TPB⁻ then starts to transfer as soon as the Galvani potential difference approaches 200 mV. The chemical composition of the adjacent phases is then altered by the Faradaic current across the interface and the redox reactions at the two electrodes connected to the external source. If instead of using TPB⁻ as the organic anion we choose a more hydrophobic anion such as tetrakis(4-chlorophenyl)borate (TPBCl⁻) for which the standard transfer potential is very large, then a positive polarization of the interface will result in the transfer of Li⁺ from water to oil (see Figure 1). It can be concluded that TPBCl⁻ is more hydrophobic than Li⁺ and is hydrophilic.

When a negative polarization is applied, then the interface is polarized until the Galvani potential difference reaches the standard transfer potential of either TBA⁺ or SO₄²⁻ ($\Delta_o^w \phi_o^{TBA^+} = -230 \text{ mV}$ and $\Delta_o^w \phi_o^{SO_4^{2-}} < -600 \text{ mV}$, respectively). Since the standard transfer potential of SO₄²⁻ is more negative than that of TBA⁺, the potential window is limited by the transfer of TBA⁺. However, if we use in the organic phase a more hydrophobic cation such as bis(triphenylphosphoranylidene) ammonium (BTPPA⁺), which has a very negative standard transfer potential, then the potential window is limited by the transfer of SO₄²⁻. Again, it can be concluded that BTPPA⁺ is more hydrophobic than sulfate is hydrophilic.

Standard Gibbs energies of ion transfer have been tabulated in different reviews.\(^{22,57–59}\)

2.2 Structure of the Interface and Potential Distribution

A liquid/liquid interface is by definition a molecular interface between two condensed media. The solvent dynamics results in an interface fluctuating to a certain limit following the capillary wave theory. If we take a time average view of the interface, we can say that it is composed of a thin (i.e. about 1 nm) mixed solvent layer. Snapshots from molecular dynamics computer simulation show that the local structure of the interface is greatly influenced by the presence of ionic charges.\(^{38,47,49,51,60,61}\)
As discussed above, the interface between two immiscible electrolytes can be polarized using an external source. From an experimental viewpoint, it is usual to operate with a four-electrode potentiostat comprising two reference electrodes and two counter electrodes to provide the current. As illustrated in Figure 2.

At the interface, the polarization is distributed over the two back-to-back Gouy–Chapman diffuse layers. One of the key unresolved issues is the dependence of the interfacial electric field on the applied polarization. At the point of zero charge, it is usually accepted that there is no specific orientation of dipoles resulting from the molecular interactions between the solvent molecules. However, it is difficult to estimate if the applied polarization influences the orientation of the solvent molecules and to quantify the strength of the field. Some authors choose, as in bioelectrochemistry, a constant-field approach to model the polarized interface, as shown in Figure 3.

2.3 Charge-transfer Reactions

2.3.1 Simple Ion Transfer

From a practical viewpoint, the kinetics of ion transfer can be considered as very fast, such that it can be assumed that the surface concentrations always follow the Nernst equation (4). In electrochemical nomenclature, it is then said that ion-transfer reactions are reversible. Similarly to a reversible redox reaction on an electrode that is limited by the mass transfer of the reactants to the electrode and by that of the products away from the electrode, an ion-transfer reaction is limited by the mass transfer of ions to the interface and away from it. Hence the mass transport differential equations and boundary conditions are similar in both cases, and all the electroanalytical methodology can therefore be transposed to the study of ion transfer reactions.

As in classical amperometry, the response of the system stems from the resolution of the diffusion equations of the ion in the two adjacent phases (Equation 10):

\[
\frac{\partial c_i^w}{\partial t} = D_w \frac{\partial^2 c_i^w}{\partial x^2} \quad \text{and} \quad \frac{\partial c_i^o}{\partial t} = D_o \frac{\partial^2 c_i^o}{\partial x^2}
\] (10)

By taking the interface as the origin, the current is then simply given by the flux of \( i \) across the interface of area \( A \) (Equation 11):

\[
I = z_i FA \left( \frac{\partial c_i^w}{\partial x} \right)_{x=0}
\] (11)

The boundary conditions are the Nernst Equation (4) and the equality of the fluxes (Equation 12):

\[
D_w \left( \frac{\partial c_i^w}{\partial x} \right)_{x=0} + D_o \left( \frac{\partial c_i^o}{\partial x} \right)_{x=0} = 0
\] (12)

2.3.2 Facilitated Ion Transfer

Assisted ion-transfer reactions are also very fast and can be considered reversible in most cases. However, mass
transport is more complicated and, as shown schematically in Figure 4, we can distinguish four types of reactions:

- aqueous complexation followed by transfer (ACT)
- transfer by interfacial complexation (TIC)
- transfer by interfacial decomplexation (TID)
- transfer followed by organic-phase complexation (TOC).

In each case, we have to consider the mass transport of the ions and of the ligands to and away from the interface. This leads to many specific cases, which have been treated in the literature (see section 4.2). More interesting from an electroanalytical aspect are the two limiting cases where either the ions or the ligands are in excess in their respective phases. In these two cases, the mass transport is limited by that of the ligand or that of the ions, respectively.

Assisted, or facilitated, ion transfer was first reported in 1979 by Koryta, who observed that the transfer of potassium and sodium ions in the aqueous phase was facilitated by the formation of a complex in the organic phase with the synthetic polyether dibenzo-18-crown-6 (DB18C6) and with the natural antibiotic valinomycin, respectively. This work was a landmark in ITIES research, because it meant that both potential window-limiting species and neutral ionophore molecules were amenable to study. As a result, this field spread quickly to solvent extraction and purification, detection of trace ions, assisted transfer of proton and development of amperometric sensors (see also section 4).

3 ANALYTICAL METHODS

3.1 Cyclic Voltammetry

Cyclic voltammograms produced by reversible ion-transfer reactions are similar to those obtained for reversible electron-transfer reactions at a metal/electrolyte solution interface, as shown in Figure 5. Thus, for reversible transfer reactions of an ion across a large (or planar) interface, the maximum forward peak current $I_{p}^{\text{FWD}}$ may then be expressed by the Randles–Sevcik Equation (13):

$$I_{p}^{\text{FWD}} = 0.4463 z_{i}FAC_i^{\omega} \sqrt{\frac{z_{i}FD_i^{\omega}V}{RT}}$$

$$\Delta \phi \omega_{\text{TMA+}} = 0.16 \text{ V}$$

Figure 5 Cyclic voltammogram for the transfer of tetramethylammonium across the water/1,2-DCE interface at different sweep rates (the interfacial area is 1.13 cm²).
where \( A \) is the interfacial area, \( \nu \) the rate of a potential sweep and \( c_w^i \) the aqueous bulk concentration of \( i \).

Together with the evaluation of the diffusion coefficient of the transferring ion, the determination of the formal transfer potential of an ion (and thus of its Gibbs energy of transfer) is the most important application of cyclic voltammetry. For a reversible ion-transfer reaction at a large planar interface, \( \Delta_n^w \phi_1^\nu \) may be expressed in terms of the half-wave potential, \( \Delta_n^w \phi_{1/2} \), by Equation (14):

\[
\Delta_n^w \phi_{1/2} = \Delta_n^w \phi_1^\nu + \frac{RT}{2z_iF} \ln \left( \frac{D_o^\nu}{D_1^\nu} \right) \tag{14}
\]

Experimentally, \( \Delta_n^w \phi_{1/2} \) is considered equal to the mid-peak potential, and is directly deduced from the voltammograms. However, as the diffusion coefficients in the organic phase are rarely known because of experimental difficulties, the ratio \( D_o^\nu/D_1^\nu \) in Equation (14) is usually approximated to the inverse ratio of the solvent viscosities, \( \eta \), by application of Walden’s rule (Equation 15):

\[
\frac{D_o^\nu}{D_1^\nu} = \frac{\eta_1^\nu}{\eta_o^\nu} \tag{15}
\]

Finally, for a reversible charge transfer, the classical following conditions also apply:

- the peak potentials must be independent of the scan rate
- the peak-to-peak separation is \( 59/z_i \) mV at 25°C.

### 3.2 Dropping-electrolyte Electrode

In the same way that the mercury-drop electrode permits very reproducible measurements owing to the continuous renewal of the interface for every drop, the dropping-electrolyte electrode allows the study of both ion-transfer and facilitated ion-transfer reactions (13,65–77). This approach has been widely used to study facilitated ion transfer. The principle consists in either dropping down or dropping up an electrolyte solution and recording the current as in polarography. The methodology of polarography can then be transposed directly.

### 3.3 Micro Interface Between Two Immiscible Electrolyte Solutions

#### 3.3.1 Micropipets and Microholes

Microelectrodes benefit from diffusion fields controlled by the geometry of the interface and from reduced ohmic loss. Because studies at ITIES always involve the use of an organic solvent, much effort has been dedicated to supporting micro liquid/liquid interfaces. Using the

Figure 6 Video micrograph of a 15.5 µm radius micropipet filled with an aqueous KCl solution and immersed in a 1,2-DCE solution of DB18C6. No external pressure was applied, and the micro ITIES is flat. The insets show the corresponding steady-state voltammograms of facilitated transfer of potassium. (Reprinted with permission from Y. Shao, M.V. Mirkin, ‘Voltammetry at Micropipet Electrodes’, *Anal. Chem.*, **70**, 3155–3161 (1998). Copyright 1998 American Chemical Society.)
micropipet technology developed for electrophysiology, liquid/liquid interfaces were first supported at the tip of micropipets, the water phase being usually located inside the pipet.\(^{(62,78–87)}\) Micropipets provide an asymmetry of diffusion fields. Ingress motion of ion occurs by pseudospherical diffusion to a microdisk interface whereas egress motion out of the pipet occurs by linear diffusion. This yields asymmetric voltammograms as shown in Figure 6. The ingress current reaches a steady-state value proportional to the radius, the diffusion coefficient and to a geometric factor.

Another approach is to support micro liquid/liquid interfaces in a microhole in a thin polymer film or in a silicon structure.\(^{(88–95)}\) A technique often used to micromachine polymers is UV laser photo-ablation,\(^{(96,97)}\) whereas that used to machine silicon is anisotropic etching. For microinterfaces supported in microholes, the thinner is the supporting film the more symmetric are the diffusion fields. For very thin films, the mass transport equations are similar to those for a microdisk electrode of radius \(r\).\(^{(88,93)}\) In this case, the half-wave potential is given by Equation (16):

\[
\Delta_0^{\alpha} \Phi_{1/2} = \Delta_0^{\alpha} \Phi^i + \frac{RT}{z_i F} \ln \left( \frac{D_0^{\alpha}}{D_i^{\alpha}} \right)
\]  

(16)

and the steady-state current by Equation (17):

\[
I_{SS} = 4z_i F D_i^{\alpha} C_o^{\alpha} r
\]  

(17)

With thicker films, however, the microhole supporting the ITIES modifies the mass transport, and both the ingress and egress geometries in and out of the microhole interface must be introduced.\(^{(98,99)}\) Following the shape given in Figure 7, the expression of the half-wave potential then becomes Equation (18):\(^{(100)}\)

\[
\Delta_0^{\alpha} \Phi_{1/2} = \Delta_0^{\alpha} \Phi^i + \frac{RT}{z_i F} \ln \left( \frac{D_0^{\alpha}}{D_i^{\alpha}} \cdot \frac{h_w + \pi r/4}{h_o + \pi r/4} \right)
\]  

(18)

The main advantage of working with microliquid/liquid interfaces stems from the low \(IR\) drop, which provides clean voltammetric responses.

### 3.3.2 Ionodes

The major barriers to the electroanalytical exploitation of amperometry at liquid/liquid interfaces have been the mechanical stability of the interface and the resistivity of the organic phase. To circumvent these difficulties, the first approach has been to “gelify” one of the phases (usually the organic phase) using the methodology developed to produce polymer membranes for the design of ISEs [see Figures 8 and 9a and b].

Recently, new composite membranes comprising an organic electrolyte gel supported on a thin polymer.
Ultraviolet/visible (UV/VIS) absorption measurements can be carried out when the incident light beam impinges on the interface from the phase of larger optical index in total internal reflection (TIR) geometry, i.e. with an incidence angle greater than the critical angle, so that the transmitted light wave in the adjacent phase cannot propagate. Voltabsorptometry measures then the changes of light intensity of the reflected beam due to absorption of charge-transfer products. Assuming that the absorbance $A_{TIR}$ is proportional to the integral of the bulk concentration of the absorbing species, its time derivative is again proportional to the Faradaic current.$^{110}$ As an example, Figure 10(a) and (b) show the evolution of the absorbance in 1,2-DCE upon transfer of methyl orange. The evolution of the UV/VIS spectra follows the current change in the corresponding voltammogram. The band at 420 nm increases monotonically during the forward sweep owing to deprotonated methyl orange transfer from water to 1,2-DCE, and decreases only after the corresponding isobestic point after which the transfer is inverted.

This technique has also been used to study Cu(II) transfer assisted by 6,7-dimethyl-2,3-di(2-pyridyl)quinoxaline, the absorption spectrum of which changes when it forms a complex. The transfer of rose bengal and eosin B has been studied by voltfluorometry,$^{111–114}$ where, similarly to UV/VIS experiments, the change in fluorescence intensity from an exciting beam is monitored as a function of applied interfacial potential.

The advantage of fluorescence and luminescence measurements is that the technique is extremely sensitive, and that small changes in interfacial concentration can be readily monitored. In contrast to cyclic voltammetry, these techniques are totally specific to the transferring...
species and are not influenced by the transfer of undesired species, such as supporting electrolyte ions. Furthermore, they are insensitive to double-layer charging and ohmic drop, so that chronoabsorptometry and chronofluorimetry studies proved to be very attractive in measuring the kinetics of ion-transfer, for which reliable data were previously difficult to obtain. Other spectroscopic techniques are also of interest in this field, such as time-resolved laser-induced fluorescence for monitoring the lifetimes of excited species and potential-modulated reflectance spectroscopy, where the transfer kinetics of a species are estimated by measuring its frequency-dependent absorption following an ac potential perturbation.

4 APPLICATIONS

4.1 Amperometric Ion Sensors and Detectors

Nonredox ionic species can be detected amperometrically by measuring the current associated with ion-transfer reactions across a polarized ITIES. However, the major difficulties in designing transducers with liquid/liquid systems stem from the mechanical instability of the ITIES and from the resistive nature of the organic phase. As can be deduced from section 3.3, these two problems can be circumvented by using microinterfaces such as micropipets and microholes in thin polymer films or by gelifying one or two of the phases (although the diffusion coefficient of ions in a gel is much reduced).

Plasticized polymers have been used to solidify the organic phase and efficient sensors for sodium, ammonium, choline and urea have been obtained by immobilizing DB18C6 within the organic phase to facilitate the transfer of Na⁺ and NH₄⁺, which were detected amperometrically. Moreover, micro liquid/liquid interface arrays have been developed for the assay of urea and creatinine, where the transducer relied again on the amperometric detection of ammonium.

Amperometric detection of choline using either direct ion-transfer or stripping ion-transfer reactions has been achieved with a water/o-nitrophenyl octyl ether (NPOE)–PVC gel interface supported on an array of microholes. Otherwise, the electrochemical behavior of NPOE gellified with 1,3; 2,4-dibenzylidene sorbitol (DBS) has been characterized and a NPOE–PVC gel has been used to manufacture an amperometric sensor for alkali metal ions by incorporation in the organic gel of ionophores such as DB18C6 and valinomycin, which has been shown to facilitate discriminitantly the transfer of lithium, sodium, ammonium and potassium. This principle has also been used to detect lithium in samples such as blood serum that contains a large excess of sodium (dibenzyl-14-crown-4 and o-nitrophenyl phenyl ether were used as ionophore and organic phase, respectively). These last two results are very promising, because they constitute a powerful alternative to conductimetric detection of nonredox species in ion-exchange chromatography, which suffers from a lack of selectivity compared with optical or direct amperometric detectors (see Figure 11a and b).

4.2 Analytical Aspects of Metal Extraction

The chemical analysis of liquid solutions has for a long time been a very important domain of analytical chemistry. Numerous applications in biology,
medicine and environmental studies require the sensitive and selective detection of chemical constituents in different media. Heavy metals are an example where the need for a precise analytical tool is of major importance owing to their high toxicity towards life in general and people in particular.

Electrochemistry at the ITIES has attracted much attention in this field during the last decade, because it provides a simple way of measuring the stoichiometry and the association constants of ion–ionophore complexes in organic solvents. With the rapid development of coordination chemistry, numerous ligands with specific binding properties have become available, extending complexation reactions where the transfer of a monocharged metal ion is facilitated by the formation of a complex of 1:1 ion-to-ligand stoichiometry to more complicated systems.

Theoretical studies on facilitated ion-transfer reactions now provide a reliable framework to analyze experimental data and to determine the physicochemical parameters governing complexation reactions at ITIES. Matsuda et al. published a general theoretical equation for the polarochemical response of reversible facilitated ion-transfer reactions, leading to a prediction of the half-wave potential dependence on the initial concentrations of both the metal and the ionophore (denoted \( \alpha \text{Init} \) and \( \alpha \text{Linit} \)). In ligand excess, the transfer is limited by the diffusion of the free metal ions towards the interface, whereas it is limited by the diffusion of the complex away from the interface in metal excess. Between these two limiting cases, a mixed diffusion regime is established and, for 1:1 stoichiometry, the authors determined criteria separating these three regions in which the dependence of \( \Delta \phi_{1/2} \) on the initial concentrations changes (see Figure 12a and b). They further described a simple method to calculate the association constants, and this work has been widely used to interpret both polarographic and cyclic voltammetric experiments.

Few studies have been carried out to model cyclic voltammetric experiments and the approach followed by Matsuda et al. has recently been generalized to 1:m ion-to-ligand stoichiometries, showing that variations of \( \alpha \text{Init} \) and \( \alpha \text{Linit} \) do not lead to a similar evolution of \( \Delta \phi_{1/2} \). This is illustrated in Figure 12(a) and (b) and demonstrated by the relationships obtained for the TIC, TID and TOC mechanisms (Equations 19–21):

\[
\Delta \phi_{1/2} = \Delta \phi_{M^{z+}}^{\alpha \text{Init}} - \frac{RT}{\alpha F} \ln \sum_{j=0}^{m} \beta_j \alpha \text{Linit}^{(j-1)} \quad (19)
\]

when \( \alpha \text{Linit} \gg \alpha \text{Init} \):

\[
\Delta \phi_{1/2} = \Delta \phi_{M^{z+}}^{\alpha \text{Init}} - \frac{RT}{\alpha F} \ln \sum_{j=0}^{m} \beta_j \alpha \text{Linit}^{(j-1)} \quad (20)
\]

where \( \beta_j \) are the reduced association constants, defined as

\[
\beta_j = \frac{c_0^{\alpha \text{Linit}}}{c_0^{\alpha \text{Init}}(c_L^j)} = \frac{K_{\alpha \text{Linit}}^j}{K_{\alpha \text{Init}}^j} \quad (21)
\]
The transfer of alkali metal cations such as Li⁺, Na⁺, K⁺, Rb⁺, Cs⁺ and Tl⁺ is facilitated by DB18C6\(^{71,131,153,154}\) and some of them by monensin, valinomycin, nigericin,\(^{155}\) nonactin\(^{156}\) and various crown ethers.\(^{1,10,15}\) The transfer of alkali earth metal ions such as Mg\(^{2+}\), Ca\(^{2+}\), Sr\(^{2+}\) and Ba\(^{2+}\) is facilitated by various water-soluble and insoluble crown ethers and by poly(oxyethylene)octylphenyl ethers\(^{158}\) and calix[4]-arene.\(^{159}\) The transfer of the alkali and alkaline earth metal ions is also facilitated by other synthetic neutral ionophores.\(^{160,161}\) Various studies were carried out with 1,10-phenanthroline, which forms complexes with heavy metal ions such as Cd\(^{2+}\), Zn\(^{2+}\), Co\(^{2+}\), Ni\(^{2+}\), Mn\(^{2+}\),\(^{72}\) and Cu\(^{2+}\),\(^{76}\) and also with protons\(^{68,162}\) and alkali and alkaline earth metal cations in various stoichiometries.\(^{163}\) 8-Quinolinol (Ni\(^{2+}\)), hydroxy oximes (Cu\(^{2+}\)) and dithizones (Ni\(^{2+}\), Zn\(^{2+}\) and Cd\(^{2+}\)) have been used for solvent extraction of these metals.\(^{164,165}\) Thio-crown ligands such as 1,4,7,10-tetrahydrocyclopentadecane facilitate the transfer of Cu\(^{2+}\),\(^{166–188}\) Cu\(^{2+}\),\(^{168,169}\) Hg\(^{2+}\),\(^{168}\) Ag\(^{+}\),\(^{168,170}\) Ni\(^{2+}\),\(^{171}\) and Pb\(^{2+}\) and Cd\(^{2+}\) and extraction of lanthanide ions has been achieved with 1,4,10,13-tetraaza-7,6-diazacyclodecane.\(^{173}\)

Likewise, ethylenediamines of different hydrophobicities have been shown to form complexes of various stoichiometries with Ni(II).\(^{174}\) Complexes of 1:1 to 1:3 stoichiometries have been clearly identified for the transfer of Ni(II), Zn(II), Fe(II) and Fe(III) assisted by the bidentate ionophores \(o,\alpha'-\)bipyrindine and \(\alpha,\beta\)-phenanthroline\(^{175}\) and for that of Co\(^{2+}\),\(^{176}\) and Cd\(^{2+}\)\(^{177}\) assisted by 2,2'-bipyridine. Similar investigations were made with the terdentate ligands 2,2',2'-terpyridine\(^{178}\), and 2,2',6',2'-terpyridine\(^{179}\) that form stable 1:1 and 1:2 complexes with transition metals\(^{178}\) and with the tetradentate phosphorus–nitrogen ligand \(N,N'-\)bis[2-(diphenylphosphino)phenyl]propane-1,3-diamine for the complexation of Co\(^{2+}\).\(^{180}\) Dihydroxynaphthalene has also been used as a complexing agent to detect Mo\(^{181}\) and cupferron to detect Al\(^{182}\), Cr\(^{183}\), U\(^{184}\), V\(^{185}\) and Eu\(^{186}\).

The facilitation effect of drug molecules such as valinomycin,\(^{7,140,187}\) monensin,\(^{188}\) nigericin,\(^{155}\) picroxan,\(^{189}\) creatinine,\(^{91}\) terramycin,\(^{190}\) rifamycin,\(^{191}\) lidocaine and dicaine\(^{192}\) has also been studied, as well as the transfer of U, Np and Pu ions facilitated by phosphine oxide.\(^{193}\) Finally, phosphine ligands have been used successfully to separate simultaneously Pb\(^{2+}\), Zn\(^{2+}\), Co\(^{2+}\), Fe\(^{2+}\), Cd\(^{2+}\), Mn\(^{2+}\) and Ca\(^{2+}\).\(^{92}\) Polarographic and molecular dynamics studies have also been introduced as methods for the calculation of complex association constants in polar solvents\(^{194–198}\) and for the determination of the structural conformation of various crown ether complexes, respectively.\(^{199–201}\) Recently, complex formation at ITIES has also been studied by SHG suggesting that a reorientation of the ionophore occurs before the complexation and the transfer of the metal ion take place.\(^{202,203}\)

This listing shows the variety of the systems studied, and a complete review and discussion of the advances in assisted ion-transfer reactions at the ITIES up to 1993 have been published.\(^{23,24}\) However, most of the above reactions follow a TIC or TID mechanism, and only a few studies show evidence of an ACT mechanism,\(^{158,204}\) because most ligands used in electrochemistry are poorly soluble in water, so that complexes may only be formed in the organic phase. Furthermore, the TOC mechanism has not been differentiated from the TIC mechanism, because this necessitates kinetic data that still remain unmeasurable, the diffusion being the factor limiting the transfer and not the energy required to allow the ions to cross the interface.

### 4.3 Lipophilicity of Ions

Because of their intrinsic nature, interfaces between two immiscible liquids may serve as simple artificial models of biological membranes. Therefore, studies on drug transfer characteristics and mechanisms in such systems are of great importance to understand better the behavior of drugs in their pharmacokinetic phase,\(^{205,206}\) their distribution in vivo\(^{207}\) and hence the delivery problems that limit their efficiency.\(^{208–211}\) The transport of exogeneous chemicals (and hence of the majority of common drugs) is a passive process,\(^{212}\) for which it is commonly assumed that ionizable compounds can only cross biological membranes in their neutral form.\(^{213}\) However, recent studies suggest a significant passive transfer of ions.\(^{214–217}\) As many drugs are organic compounds that are thus partly or largely ionized at physiological pH, membrane transport can be deeply affected by the lipophilicity of charged species.\(^{218}\) The lipophilicity of a species is generally evaluated by its partition coefficient, defined as the logarithm of the ratio of the activity of a species in the organic phase to that in the aqueous phase and denoted log \(P\). This parameter is widely used in medicinal chemistry to relate the structure and the physicochemical properties of a drug to its biological activity,\(^{219}\) which is the objective of all quantitative structure–activity relationship (QSAR) studies.\(^{220}\)

Dealing only with ions for which \(\log P\) is directly given by the formal transfer potential,\(^{221}\) electrochemistry at the ITIES appears to be a method of choice for assessing the lipophilicity of ionizable drugs. The literature is still very scarce on this topic, and ion-transfer voltammetry has only been applied to determine the transfer potentials of a few compounds of biological interest.
Figure 13 Ionic partition diagram of trimetazidine at 25°C in water–1,2-DCE. The figure shows the formal transfer potentials obtained by cyclic voltammetry as a function of aqueous pH (bold circles), the equiconcentration lines between two adjacent species (bold dashed lines) and the corresponding transfer mechanisms (chemical equilibria). T, TH+ and TH2+ stand for the neutral, the singly protonated and the doubly protonated forms of trimetazidine, respectively. (Adapted from Reymond et al.247 by permission of Plenum Publishing Corporation.)

[1,10-phenanthroline,68,222] acetylcholine,125,223–225 various amines,77,226,227 phosphorylation uncouplers,228,229 pyrazolone derivatives,230 picate,63,231–233 cinchonidine75 and quinine74,221,234,235] and to investigate the transfer of several antibiotics236–239 and of a series of hypnotic, anesthetic, cholinergic and adrenergic agents.192,240–243 However, the recent introduction of ionic partition diagrams244 (which are a transposition at liquid/liquid interfaces of Pourbaix's pH–potential diagrams244 for metals in solution) has improved the understanding of the partition processes of ionizable compounds, since they allow reliable predictions and interpretations of their transfer mechanisms across ITIES, as exemplified by Figure 13 for the case of trimetazidine. Further insight into the influence of electronic structure on lipophilicity has revealed the importance of intramolecular charge delocalization to stabilize ions in the organic phase.245–248 Although this effect has not yet been quantified, electrochemistry at ITIES is an easy methodology to assess the pH–lipophilicity profiles of ionizable drugs, and it should soon become increasingly popular.

It must finally be noted that octanol is not polarizable,249 so that most electrochemical studies use 1,2-DCE or nitrobenzene as the organic phase. In order to interpret the lipophilicity of ionizable drugs in pharmacological terms, the thermodynamic parameters obtained with these solvents must be correlated to the octanol–water system commonly used in pharmacology. This correspondence has been established,250 offering more relevance to the results presented above and opening ideal perspectives for extending electrochemical measurements to medicinal chemistry.

5 CONCLUSION

The increasing number of experiments conducted at liquid/liquid interfaces shows that electrochemical methodologies at such boundaries can be an efficient and versatile tool to probe ions. The great demand for innovative analytical techniques with accurate sensitivity and high selectivity offers a brilliant future for ITIES. Solvent extraction, separation, transfer-phase catalysis and biomembrane studies are other areas where ITIES are expected to develop rapidly.

Further, the study of charge-transfer processes gives an insight into the fundamental problems of physical chemistry in biphasic systems. Thanks to the improved theoretical understanding of interfacial structure, the transfer process of solvated ions from one phase to the other becomes clearer, but it is still very demanding because future applications of ITIES will depend on our theoretical knowledge of the motion of ions in biphasic systems.

Nevertheless, the above applications still suffer from a lack of experimental information compared with other techniques, and further investigations are required.

The need for direct measurement of interfacial events at solid surfaces under ambient conditions has provoked surface scientists and electrochemists to develop direct in situ methods. Such processes include electroless or electrochemical metal deposition, insertion of ions into polymer ion-exchange films, growth of oxide films on metals, or the loss of material from corrosion processes. An increasing interest in molecular films has prompted development of methods for measuring adsorption of molecules from vapor or liquid phases. Many of these processes share a common feature, namely they are accompanied by changes in mass at the solid surface.

During the 1990s a new analytical method for the in situ examination of interfacial electrode processes, the electrochemical quartz crystal microbalance (EQCM), has emerged that has substantially influenced electrochemical science. This method relies on a single crystal of quartz that has been cut into a thin wafer and coated with gold electrodes on both sides. These electrodes are used to provide an alternating electric field so that the crystal is vibrated at a specific resonant frequency, while one of the electrodes is simultaneously used as a working electrode in an electrochemical cell. The resonant frequency shifts upon changes in mass that occur on the working electrode during an electrochemical process, with sensitivity as high as 100 pg cm\(^{-2}\) of electrode area. Recent developments also have illustrated that the quartz crystal microbalance (QCM) is capable of measuring the viscosity and density of liquids near the QCM surface. The purpose of this article is to provide the reader with a fundamental understanding of the EQCM and several illustrative examples of applications that demonstrate its unique capabilities, as well as the technical details required to build this apparatus.

1 INTRODUCTION

In the 1980s and 1990s surface scientists and electrochemists have made considerable strides in sophisticated instrumental techniques for probing the structure and composition of solid interfaces and electrodes, motivated by the need to measure and understand interfacial processes. However, many of these techniques involve examination of solid surfaces outside the medium in which they are typically used. For example, ultrahigh vacuum studies of electrode and catalyst surfaces provide invaluable data concerning structure and composition. The relevance of data obtained from such ex situ methods to properties and applications under ambient conditions, particularly applications involving immersion of the surface in solution, can be questionable.

The need for direct measurement of interfacial events at solid surfaces under ambient conditions has provoked surface scientists and electrochemists to develop direct in situ methods. In addition to providing data that can be used for understanding fundamental mechanistic details, in situ approaches can be useful in sensor applications where measurement under specific, and sometimes harsh, conditions is required. Such processes include electroless or electrochemical metal deposition, insertion of ions into polymer ion-exchange films, growth of oxide films on metals, or the loss of material from corrosion processes.
An increasing interest in molecular films has prompted development of methods for measuring adsorption of molecules from vapor or liquid phases. Many of these processes share a common feature, namely they are accompanied by changes in mass at the solid surface.

In the 1990s, a new analytical method for the in situ measurement of interfacial electrode processes, the EQCM, has emerged that has substantially influenced electrochemical science. This method relies on the piezoelectric properties of a single crystal of quartz that has been cut into a thin wafer. The word piezoelectric derives from the word piezein, meaning to press. Hence, the piezoelectric effect hinges on “pressure electricity,” a phenomenon first observed by Jacques and Pierre Curie when they discovered that mechanical stress applied to the surfaces of certain crystals, including quartz, resulted in an electrical potential across the crystal. Shortly afterwards, the converse piezoelectric effect—a mechanical strain produced by application of an electric potential across the crystal—was discovered. This effect is sometimes referred to as the converse piezoelectric effect. The motor generator properties have long been associated with underwater sound transducers (sonar), and electromechanical devices such as speakers, microphones, and phonograph pickups.

The QCM earns its name from its ability to measure the mass of thin films that have adhered to its surface. The QCM generally comprises a thin quartz wafer with a diameter of 0.25–1.0 in (1 in = 2.54 × 10^{-2} m), sandwiched between two metal electrodes which are used to establish an electric field across the crystal. If an alternating electric field and appropriate electronics are used, the crystal can be made to oscillate at its resonant frequency. Most crystals of current interest resonate between 5 and 30 MHz. The measured frequency is dependent upon the combined thickness of the quartz wafer, metal electrodes, and material deposited on the QCM surface. Because the resonance is very sharp, high-precision frequency measurements allow the detection of minute amounts of deposited material, as small as 100 pg cm^{-2}.

Early applications of the QCM involved the well-documented measurement of metal deposition in high-vacuum metal evaporators, which is still widely practiced. This allows for real-time rapid measurement of film thicknesses with ångström resolution (1 Å = 10^{-10} m). Advances in QCM methodology in the 1990s allow for dynamic measurements of minute mass changes at surfaces, thin films, and electrode interfaces prepared on the quartz crystal, while the surface is immersed in liquid. The capability for direct real-time highly sensitive mass measurement in the liquid phase offers opportunities not available by other means. Developments also have illustrated that the QCM is capable of measuring the viscosity and density of liquids near the QCM surface. Combining this technique with electrochemical instrumentation allows simultaneous measurement of mass and electrochemical variables such as electrochemical potential, current, and charge.

The EQCM has emerged as a powerful technique capable of detecting very small mass changes at the electrode surface that accompany electrochemical processes. This relatively simple technique requires, in addition to conventional electrochemical equipment, an inexpensive radiofrequency (RF) oscillator, a frequency counter, and commercially available AT-cut quartz crystals. EQCM has evolved into a routine experimental method used in numerous electrochemical laboratories. The purpose of this article is to provide the reader with a fundamental understanding of the EQCM and several illustrative examples of applications that demonstrate its unique capabilities. It is hoped that this will enable readers to add the EQCM to their battery of electrochemical methods. Other review articles can be consulted for different emphasis or greater detail.\(^{1–3}\)

2 THEORY AND PRINCIPLES

In order to understand the operation of the EQCM a fundamental understanding of the piezoelectric effect is required. In 1880, Jacques and Pierre Curie discovered that a mechanical stress applied to the surfaces of various crystals, including quartz, rochelle salt (NaKC\(_2\)H\(_4\)O\(_6\)·4H\(_2\)O), and tourmaline, resulted in an electrical potential across the crystal whose magnitude was proportional to the applied stress.\(^4\) This behavior is referred to as the piezoelectric effect which is derived from the Greek word piezein meaning “to press.” This property only exists in materials that are acentric, that is, those that crystallize into noncentrosymmetric space groups. A single crystal of an acentric material will possess a polar axis due to dipoles associated with the arrangement of atoms in the crystalline lattice. The charge generated in a quartz crystal under mechanical stress is a manifestation of a change in the net dipole moment because of the physical displacement of the atoms and a corresponding change in the net dipole moment. This results in a net change in electrical charge on the crystal faces, the magnitude and direction of which depends upon the relative orientation of the dipoles and the crystal faces. Following their initial discovery, the Curies discovered the converse piezoelectric effect, in which the application of a potential across these crystals resulted in a corresponding mechanical strain. It is this effect that is the operational basis of the EQCM.

The EQCM is actually the electrochemical version of the QCM, which has long been used for frequency control.
and mass sensing in vacuum and air. The QCM consists of a thin, AT-cut quartz crystal with very thin metal electrode “pads” on opposite sides of the crystal. The terminology “AT” simply refers to the orientation of the crystal with respect to its large faces; this particular crystal is fabricated by slicing through a quartz rod at an angle of approximately 35° with respect to the crystallographic x axis. The electrode pads overlap in the center of the crystal with tabs extending from each to the edge of the crystal where electrical contact is made. When an electrical potential is applied across the crystal using these electrodes, the AT-cut quartz crystal experiences a mechanical strain in the shear direction. Crystal symmetry dictates that the strain induced in a piezoelectric material by an applied potential of one polarity will be equal and opposite in direction to that resulting from the opposite polarity (Figure 1). Therefore, an alternating potential across the crystal causes vibrational motion of the quartz crystal with the vibrational amplitude parallel to the crystal surface and in the x-direction. This oscillatory behavior and the electromechanical “motor generator” properties are the basis of numerous applications, including the QCM, sonar transducers, speakers, microphones, phonograph pickups, and quartz digital watches. It is important to note that the direction of the crystal vibration is critical for liquid-phase applications. An AT-cut crystal vibrates in the shear mode, parallel to the crystal—liquid interface. Consequently, damping of the crystal vibration by a contacting fluid are minimized (see below).

The shear vibrational motion of the quartz crystal results in a transverse acoustic wave that propagates back and forth across the thickness of the crystal between the crystal faces. Accordingly, a standing wave condition is established in the quartz resonator when the acoustic wavelength is equal to twice the combined thickness of the crystal and electrodes. The frequency, \( f_0 \), of the acoustic wave fundamental mode is given by Equation (1), where \( v_{tr} \) is the transverse velocity of sound in AT-cut quartz (3.54 × 10^5 m s\(^{-1}\)) and \( t_0 \) is the resonator thickness. Some useful parameters and relationships for quartz resonators are provided in Table 1. An assumption is commonly made that the velocity of sound in quartz and the electrodes is identical. While this is not rigorously true, for small electrode thicknesses the error introduced by

\[
t = 3\pi/2\omega; x = -x_{\text{max}}
\]

\[
t = 0; x = 0
\]

\[
t = \pi/2\omega; x = +x_{\text{max}}
\]

![Figure 1](a) Schematic representation of the shear vibration of an AT-cut quartz resonator. The time at which the crystal achieves maximum strain during oscillation is indicated. The crystal has maximum kinetic energy at \( x = 0 \), but maximum potential energy at \( x = \pm x_{\text{max}} \), similar to classical oscillators. (b) Schematic representation of the transverse shear wave in a quartz crystal with excitation electrodes and a composite resonator comprising the quartz crystal, electrodes, and a thin layer of a foreign material. The acoustic wavelength is longer in the composite resonator because of the greater thickness, resulting in a lower frequency compared to the quartz crystal.

this approximation is negligible. The acoustic velocity is dependent upon the modulus and density of the crystal. The quartz crystal surface is at an antinode of the acoustic wave, and therefore the acoustic wave propagates across the interface between the crystal and a foreign layer on its surface. If it is assumed that the acoustic velocity in the foreign layer, and its density, are identical to those for quartz (cf. the assumption for the metal electrodes), a change in thickness of the foreign layer is tantamount to a change in the thickness of the quartz crystal. Under these conditions, a fractional change in thickness results in a fractional change in the resonant frequency; appropriate substitutions yield the well-known Sauerbrey equation, Equation (2), where $\Delta f$ is the measured frequency change, $f_0$ the frequency of the quartz resonator prior to a mass change, $\Delta m$ the mass change, $A$ the piezoelectrically active area, $\rho_Q$ the density of quartz ($2.648 \text{g cm}^{-3}$) and $\mu_Q$ the shear modulus of AT-cut quartz ($2.947 \times 10^{11} \text{ dyn cm}^{-2}$) ($1 \text{ dyn} = 10^{-5} \text{ N}$).

$$f_0 = \frac{\nu_{tr}}{2\mu_Q}$$ (1)

$$\Delta f = -\frac{2f_0^2 \Delta m}{A\sqrt{\mu_Q\rho_Q}}$$ (2)

This equation is the primary basis of most QCM and EQCM measurements wherein mass changes occurring at the electrode interface are evaluated directly from the frequency changes of the quartz resonator. It is generally considered to be accurate as long as the thickness of the film added to the QCM is less than 2% of the quartz crystal thickness. With this constraint, the errors resulting from the discrepancy between the acoustic propagation characteristics in quartz and the film are minimal. Deviations from Equation (2) due to higher mass loadings may be compensated, however, by use of the “Z-match” method.\(^{[5]}\) While this method has been used for vacuum applications, it has yet to be employed in EQCM applications. Typical operating frequencies of the EQCM of the QCM lie within the range 5–10 MHz, although recently the operation of 30 MHz quartz crystals in EQCM applications has been achieved.\(^{[6]}\) These operating frequencies provide for mass detection limits approaching 1 ng cm\(^{-2}\).

The reader may better understand the mass sensing properties of the QCM by comparing the motion of the quartz crystal to other oscillating systems, such as a vibrating string, a pendulum, or a mass on a spring. In all cases the amplitude is defined by the initial energy input and the resonant frequencies are defined by characteristics of mass and length. The quartz crystal motion can be described as moving about the $x = 0$ rest point between limits of $-x_{max}$ and $+x_{max}$. The magnitude of $x_{max}$ will depend upon the applied alternating voltage across the crystal. As with the more familiar oscillating systems, the potential energy of the crystal is at a maximum at $x = \pm x_{max}$, whereas the kinetic energy is at a maximum at $x = 0$. The effect of mass (or thickness) changes on the quartz resonant frequency can be understood by analogy to a classical system such as a vibrating string. Standing waves can exist in a vibrating string if their wavelengths are integral divisors of $2l$, where $l$ is the length of the string. The fundamental frequency, $f_0$, is given by Equation (3), where $A$ is the tension on the string and $m_i$ is the mass per unit length.

$$f_0 = \frac{(S/m_i)^{1/2}}{2l}$$ (3)

An increase in the mass or length of the string therefore results in a decrease in $f_0$. This is identical to increasing the thickness of a quartz crystal, with a dimensional increase resulting in a longer standing wave propagation distance and a corresponding reduction in the frequency. The stress applied to the vibrating string is analogous to the modulus of the quartz crystal; an increase in either of these quantities increases the velocity of the standing wave.

The key distinguishing feature of quartz resonators is their negligible energy dissipation during oscillation. While a pendulum may lose considerable energy during oscillation because of friction, a quartz crystal loses only a minute amount due to phonon interactions that produce heat, vibrational damping by the mounting components, and acoustical losses to the environment. This property is generally characterized by the quality factor, $Q$, which is the ratio of the energy stored to energy lost during a single oscillation. For quartz crystals, this quantity can exceed 100 000. Low energy losses in oscillating systems are manifested as high accuracy. As a system loses more energy during oscillation the period of the oscillation becomes less well defined. This is the basis for the widespread use of quartz crystals in timepieces and frequency control elements. In fact, the frequency of a typical quartz crystal can be determined to an accuracy of 1 part in $10^8$. It is this precision that makes the QCM and EQCM so useful. In liquid applications, including the EQCM, $Q$ will generally have values of 1000–3000, indicative of energy damping by the fluid. Nevertheless, the quartz crystals will still perform acceptably at these levels.

The vibration of the quartz crystal parallel to the QCM–liquid interface results in the radiation of a shear wave into the liquid (Figure 2). The instantaneous shear wave velocity decays as an exponentially damped cosine function according to Equation (4), where $k$ is the propagation constant, $z$ the distance from the resonator surface, $A$ the maximum amplitude of the shear wave, and $w$ the angular frequency. The inverse of the propagation
constant $k$ is the decay length, $\delta$, which is given by Equation (5), where $\rho_L$ and $\eta_L$ are the liquid density and viscosity, respectively. This leads to Equation (6), which gives the dependence of the resonant frequency on $(\rho_L\eta_L)^{1/2}$. 

$$V_s(z,t) = Ae^{-\delta z} \cos(kz - \omega t)$$  \hspace{1cm} (4)

$$\delta = \sqrt{\frac{\eta_L}{\rho_0 \rho_L}}$$  \hspace{1cm} (5)

$$\Delta f = -f_0^{3/2} \left( \frac{\rho_L \eta_L}{\rho_0 \eta_0 \mu_Q} \right)^{1/2}$$  \hspace{1cm} (6)

This effect of a contacting fluid medium is evidenced by the approximately 750-Hz decrease in resonant frequency that occurs when a QCM is immersed in water. This decrease can be attributed to the effective mass of liquid contained in this decay length. It should be noted that the viscosity of the fluid becomes larger, the accuracy and performance of the submerged quartz resonator diminishes. These effects can be especially important when the EQCM is modified with polymer films, which may undergo changes in $(\rho_L\eta_L)^{1/2}$ during measurements.

Another effect that needs to be considered when quartz resonators are immersed in liquids is the microscopic roughness of the resonator surface. The cavities on a rough surface can trap liquid which will be manifested as an additional mass on the surface. The amount of trapped liquid will depend upon the cavity geometry and size. This effect has been inferred in gold and copper surfaces on the EQCM, in which the electrode surfaces were roughened during electrochemical cycling through the oxide regions of the metal electrodes. An extensive study of these gold surfaces involved comparison of the frequency shift with that expected for liquid trapped conditions.
in surface cavities whose dimensions were measured by scanning electron microscopy (SEM). These studies indicated that the frequency changes were smaller than expected based on the SEM measurements, suggesting that the trapped liquid did not behave as a rigid mass. Therefore, surface roughness effects can be very difficult to quantify even when the exact roughness is known. These effects may be significant in many published EQCM studies because of the wide use of unpolished quartz crystals, which are commonly used because of their ready availability and low cost. These are widely sold for vacuum thickness monitor applications where good adhesion of metal films is required, but liquid trapping is not a factor. Our laboratories have always used polished quartz crystals in order to minimize roughness effects. In any case, any published work employing the EQCM should contain a description of the quartz crystals and their roughness.

3 ELECTROCHEMICAL METHODS AND EXAMPLES OF APPLICATIONS

The EQCM has been used to examine a wide variety of electrochemical processes. Unfortunately, space does not permit here a comprehensive review of the area and the reader is referred to other reviews cited earlier. Rather, this section will highlight some illustrative examples of EQCM applications which are meant to provide the reader with a general understanding of the scope of this method with respect to its capability, phenomena that affect measurements, and the types of system that are amenable to examination.

3.1 Experimental Apparatus and Operation

Several versions of EQCM instrumentation have been described (14–17) differing mostly in minor details. The system described below is one that has been developed in our laboratory (Figure 3). Commercial systems are now available (EG&G PAR, Elechema), but it has been our experience that the practitioner gains a better awareness of the strengths and limitations of the method by building the homemade system. EQCM quartz crystals commonly have diameters of 0.5 in and 1.0 in, with appropriately sized excitation electrodes. The Bechmann numbers (18–20) dictate that, for a crystal diameter that is 50 times the crystal thickness, the electrode diameter must be 18 times the crystal thickness in order to avoid interference from other acoustic modes. Accordingly, a reduction in crystal and electrode diameter must be accompanied by a corresponding reduction in the crystal thickness to maintain frequency stability.

The crystals can be mounted at the bottom of a glass cylinder that assumes the role of the working electrode compartment of an otherwise conventional electrochemical cell. The crystal is mounted so that the excitation electrode that is to be employed as the working electrode is facing the solution; the opposite electrode is therefore facing air in order to avoid electrical shorting between the electrodes. If the quartz crystal is immersed under a column of the electrolyte solution, hydrostatic pressure results in a stress on the quartz crystal that affects the resonant frequency. Equation (7) describes a parabolic dependence of \( f_0 \) on the hydrostatic pressure.
Figure 4  (a) Schematic representation of the hardware configuration for the EQCM, neglecting the electrochemical apparatus depicted in Figure 3. (b) Schematic of an oscillator circuit and related components. (c) Detailed schematic of the component layout for the oscillator circuit. The components are listed in Table 1.
However, the significance of this effect is probably minimal as the hydrostatic pressure is generally constant (barring evaporation) for most experiments. This problem can be avoided completely by configurations in which the crystal is simply mounted vertically. Crystals can be mounted between O-rings or with epoxy, the former being more convenient as the crystals can be easily demounted for reuse or further surface studies. Our laboratory has found that Teflon™-coated O-rings give the best performance.

The two excitation electrodes are electrically connected to an oscillator circuit that contains a broadband RF amplifier. Several oscillator designs are available, although standard commercial oscillators, such as those sold for metal evaporation control, typically need modification in order to supply the crystal with sufficient gain to sustain oscillation in liquids. Therefore, it is usually simpler to build the oscillator. The schematic for the oscillator circuit used in our laboratory is illustrated in Figure 4. For the convenience of the reader, a parts manifest is provided in Table 2. A commercially fabricated printed circuit board is also recommended in order to avoid noise pickup that accompanies circuit built on crude breadboards. The circuit is designed so that the crystal is in a feedback loop, therefore driving the crystal at a frequency at which the maximum current can be sustained in a zero-phase angle condition. The electrode facing solution is at hard ground. The output of the oscillator is connected to a conventional frequency meter for measurement. A critical feature of the EQCM is the type of potentiostat: the Wenking potentiostat functions with the working electrode at hard ground whereas most commercially available potentiostats generally function with the working electrode at virtual ground. Commercial potentiostats can only be used if the working electrode is not connected to the potentiostat and the potential difference between the reference and hard ground is used to control the working-electrode potential. Because the current is generally measured at the working-electrode side, this format requires that the current be measured by the voltage drop across a resistor in series with the counter-electrode connection. Because this equipment generally is available in most electrochemical laboratories, the EQCM practitioner need not build, or buy, a custom-made Wenking potentiostat. Finally, a computer is used to collect frequency and electrochemical data simultaneously, as well as control the waveform applied to the working electrode. This arrangement allows simultaneous measurement of the electrochemical charge, current, voltage, and EQCM frequency. The timescale

\[ f_0 - f_0^{\text{max}} = A(p - p_{\text{max}})^2 \]  

(7)

</table>

of the analysis is in a particularly useful domain for electrochemists. The time constant of a quartz resonator is fixed by \( Q/\pi f_0 \). The quality factor for a 5-MHz resonator is \( Q \approx 10^3 \), and therefore the minimum sampling time is in the millisecond range. Frequency counters are capable of sampling the frequency output of the oscillator at 100 ms intervals. This capability enables analysis of the kinetics of a wide range of electrochemical processes, including electrodeposition and dissolution, nucleation and growth, and ion/solvent insertion in redox polymer films. It is important to stress that this equipment is not prohibitively expensive and is well within the reach, economically and technically, of most electrochemical investigators.

### 3.2 Electrochemical Measurements of Crystal Resonant Properties in Fluids

There are other aspects of the EQCM that distinguish their operation in liquids from that of the QCM in vacuum or the gas phase, namely the effect of the liquid on the actual vibrating area of the quartz crystal. The Sauerbrey equation, Equation (2), assumes that the frequency shift resulting from a localized deposit is equivalent to the contribution of that deposit when it is a portion of a thin film of identical thickness distributed over the entire active EQCM area. However, a general expression that accounts for localized or nonuniform mass deposits covering the EQCM electrode to \( r = r_e \) (where \( r_e \) is the ideal radius of the excitation electrodes, between which the electric field induces crystal motion) is given by Equation (8).

\[
\Delta f = \left( \frac{1}{\pi f_0} \right) \int_0^{2\pi} \int_0^{r_e} S(r, \theta) m(r, \theta) r \, dr \, d\theta \tag{8}
\]

where \( S(r, \theta) \) is the differential mass sensitivity (\( df/dm \)) and \( m(r, \theta) \) is the mass distribution with respect to \( r \), the distance of the deposit from the center of the crystal and \( \theta \), the angle in the crystal plane with respect to the \( x \)-axis. It has long been accepted, on the basis of theory and experiment, that \( S(r, \theta) \) has a near-Gaussian form in which the crystal vibration is maximum in the center and negligible at the edges.\(^{(23-27)}\) Indeed, Equation (8) and the Sauerbrey equation are based on the assumption that the vibrating area, and therefore the mass sensitive area, is limited to within the region where the excitation electrodes overlap. Any changes in \( S(r, \theta) \) resulting from the liquid, or any crystal motion beyond the electrode edges, will cause deviations from the ideal response.

It has been shown in liquids that \( S(r, \theta) \) and the actual vibrational area depend significantly upon the liquid and its properties, including its viscosity.\(^{(28-31)}\) EQCM measurements performed in conjunction with SEM demonstrated that \( S(r, \theta) \) was gaussian-like (Figure 5).

![Figure 5](image)

**Figure 5** Sensitivity distributions \( S(r, \theta) \) for a 5-MHz AT-cut quartz crystal determined by a SEM method in which 100-\( \mu \)m diameter circular copper features are electrodeposited at different values of \( r, \theta \) while simultaneously measuring electrochemical charge and frequency. The amplitude of these plots at a given value of \( r, \theta \) represents the sensitivity of the EQCM to mass changes at that location, and the area under the plot represents the total, or integral, sensitivity \( C_f \). The \( S(r, \theta) \) plots shown were measured on (a) plano–plano and (b) plano–convex quartz crystals in aqueous 20-mM CuSO\(_4\) (\( n_l = 0.8904 \times 10^{-2}\) g cm\(^{-1}\) s\(^{-1}\)), and (c) plano–convex quartz crystals in aqueous 20-mM CuSO\(_4\) containing 15% sucrose (\( n_l = 1.469 \times 10^{-2}\) g cm\(^{-1}\) s\(^{-1}\)). (Reproduced with permission from Hillier and Ward.\(^{(29)}\) Copyright (1992) American Chemical Society.)
However, the shape and the maximum value in the center were dramatically affected by the viscosity of the liquid in contact with the EQCM. Increasing the viscosity resulted in a suppression of the maximum and an increase in the mass-sensitive area due to a phenomenon referred to as field fringing, in which the crystal vibrations extend beyond the electrode area. This results in an overall reduction in the sensitivity of the EQCM. The details of these effects will depend upon crystal contour, electrode geometry, and the liquid properties. Trapping of the crystal vibrations within the excitation electrode boundaries is much more efficient for plano–convex crystals, in which one side of the crystal is contoured by polishing such that its shape resembles a convex lens. The difference in mass between the center and outer regions of the crystal results in a focusing of the acoustic energy toward the center of the resonator, as is evident from an increase in the value of $S(r, \theta)$ at the center and negligible mass sensitivity at $r > r_c$. Therefore, there appear to be distinct advantages to using plano–convex crystals. Understanding of these effects is crucial if precise quantitative interpretation of EQCM data is required. At the very least, these effects should be appreciated in a qualitative way.

### 3.3 Data Interpretation for Ideally Behaved Systems

Interpretation of EQCM data is accomplished in a rather straightforward manner. Since the electrochemical charge represents the total number of electrons transferred in a given electrochemical process, it corresponds to mass changes occurring at the electrode surface. Accordingly, under ideal conditions, the frequency change measured with the EQCM will be proportional to the electrochemical charge, and will be related to the apparent molar mass by Equation (9), where $MW$ is the apparent molar mass (g mol$^{-1}$), $Q$ is the electrochemical charge, $n$ is the number of electrons involved in the electrochemical process, $F$ is the Faraday constant, and $C_f$ (Hz g$^{-1}$) the sensitivity constant derived from the Sauerbrey relationship.

$$\Delta f = \frac{MW C_f Q}{nF}$$  \hspace{1cm} (9)

Inspection of Equation (9) reveals that plots of $\Delta f$ versus $Q$ are particularly useful in the determination of $MW/n$, which represents the molar mass per electron transferred. This calculation, of course, depends upon knowledge of $C_f$. Because this value can differ for different crystal contours, electrode geometries, and solution conditions (see above), it is important to calibrate the EQCM with a well-behaved electrochemical reaction under conditions similar to those present during the experiments of interest. This is generally accomplished with copper or silver electrodeposition, for which all terms on the right side of Equation (9) are known except for $C_f$. The term apparent molar mass is stressed because in many cases the measured value of $MW$ may not be that expected based on a simple stoichiometric relationship, but may involve solvent or co-adsorbed species that can reveal considerable insight into the electrochemical behavior. Nonlinearity in plots of $\Delta f$ versus $Q$ can be particularly useful for diagnosing nonideal behavior such as roughness and viscoelastic effects that may become evident over the range of frequency changes examined. An alternative approach to data analysis involves the relationship between the electrochemical current and the first derivative of the frequency change with respect to time, as given in Equation (10), where $v$ is the scan rate in units V s$^{-1}$.

This format is particularly useful for cyclic voltammetry experiments, as $d\Delta f/dt$ should appear similar in form to the voltammograms if the electrochemical events are accompanied by corresponding mass changes.

$$i = \frac{d(\Delta f)}{dE} \frac{mvF}{MW C_f}$$  \hspace{1cm} (10)

The utility of the EQCM method stems from its capability of measuring electrochemical charge and current while simultaneously measuring mass changes with extraordinary sensitivity. A typical operating resonant frequency of 5 MHz provides a theoretical sensitivity of 0.5666 Hz cm$^{-2}$ ng$^{-1}$. Since the frequency can generally be measured to within an accuracy of 1 Hz, the EQCM can detect approximately 10 ng cm$^{-2}$. This translates roughly into 10% of a monolayer of Pb atoms. Much higher sensitivity can be realized with quartz crystals that operate at a higher fundamental frequency, as the sensitivity increases with $f_0^2$. Alternatively, the quartz crystal can be driven at one of its odd harmonic modes with appropriate circuitry, which provides an $n$-fold increase in sensitivity, where $n$ is the harmonic number. While the third harmonic of a 5-MHz crystal (i.e. an operating frequency of 15 MHz) has been employed successfully in the examination of underpotential deposition (UPD) on metal electrodes,$^{[32]}$ general use of this approach can be limited by the lower stability of the harmonic modes relative to the fundamental mode.

It is much more beneficial to employ crystals that can be operated at higher fundamental frequencies. However, higher fundamental frequencies can only be achieved by fabricating thinner crystals. The operating frequency range of the EQCM has been extended as far as 30 MHz. While these crystals are rather thin ($t_0 = 50 \mu m$), they could be used conveniently by constructing the electrochemical cell with heat-shrinkable Teflon™ tubing constricted about the periphery of the crystal. In liquid media the frequency of a 30-MHz resonator responds to changes in the liquid viscosity and density according
to Equation (6). That is, these resonators exhibit a linear relationship between $\Delta f$ and $(\eta L \rho L)^{1/2}$, identical to behavior expected and observed for lower frequency resonators. Electrodeposition of copper on the EQCM surface (Figure 6) affords sensitivity constants in exact agreement with Equation (9), indicating that energy trapping of the fundamental mode is very efficient for the 30-MHz resonators (lower frequency resonators commonly exhibit sensitivity constants that are lower than expected owing to acoustic field fringing). The higher frequency resonators have many potential advantages, including greater sensitivity to mass, better signal-to-noise characteristics than other acoustic wave devices, and less energy dissipation during oscillation. The origin of the improved stability is evident from admittance analysis of 30-MHz resonators (see below). Higher frequency EQCMs are feasible if chemically milled crystals are employed. Such a crystal is obtained by chemically etching the center of a quartz crystal to obtain a thin quartz “membrane” in the center of a thicker outer quartz ring, the outer ring providing improved mechanical stability.

Changes in the depletion layer that accompany redox processes also can influence EQCM measurements. Our laboratory demonstrated that cyclic voltammetry in solutions containing the Fe(CN)$_6^{3-/4-}$ or Ru(NH$_3$)$_6^{2+/3+}$ redox couples was accompanied by potential-dependent changes in the resonator frequency even though no mass changes occurred at the electrode surface (Figure 7). This behavior can be attributed to changes in the density of the depletion layer that accompany the change in redox state. Modeling of the depletion-layer characteristics using known densities and viscosities of each redox species.
have confirmed that the frequency changes during cyclic voltammetry behaved according to Equation (6).

### 3.4 Electrochemical Quartz Crystal Microbalance Investigations of Metal Electrodes and Films

As stated above, the most common technique for calibrating the EQCM involves simultaneous measurement of the electrochemical charge and resonant frequency during the electrochemical deposition or dissolution of a metal film. This capability was demonstrated by Bruckenstein and Shay in which the deposition of 10 layers of Ag metal on a 10-MHz EQCM gave frequency shifts that were within 3% of the amount expected based on the Sauerbrey equation. Therefore, the EQCM can be an effective method for examining the Faradaic efficiencies of electroplating and dissolution processes such as corrosion.

The high sensitivity of the EQCM has enabled examination of UPD processes in situ. For example, examination of the UPD of Pb on the Au working electrode of the EQCM revealed mass and electrochemical charge changes in the UPD region corresponding to a hexagonally closest packed monolayer. The ability to measure

![Figure 8](image)

**Figure 8** (a) Frequency shift of the EQCM during Bi UPD on a Au electrode (1.0-mM Bi in 0.1-M HClO₄). (b) Current response during Bi UPD on the Au EQCM electrode (-----) and current response expected from the observed frequency response (-----). (Reproduced from Deakin and Melroy, *J. Electroanal. Chem.*, Copyright (1998) with permission from Elsevier Science.) (c) Cyclic voltammetric scan showing the current and EQCM response obtained at an EQCM silver electrode in 0.1-M borate buffer at pH = 9.15; scan rate = 50 mV s⁻¹. The electrode was conditioned at −100 mV (vs SCE) for 30 s before initiating the potential scan. (d) Cyclic voltammetric scan showing the current and EQCM response obtained at an EQCM silver electrode in 0.1-M borate buffer at pH = 9.15 containing 2.7 × 10⁻⁵ M Pb(II); scan rate = 50 mV s⁻¹; starting potential = −100 mV. (Reproduced from Hepel et al., *J. Electroanal. Chem.*, Copyright (1989) with permission from Elsevier Science.)
mass and charge simultaneously allowed determination of the electrovalency number for this process, which was found to be $\gamma = 2.08 \pm 0.10$. Similar experiments revealed that other UPD processes occurred with $\gamma$ values lower than expected for complete electron transfer, with $\gamma_{\text{Bi}} = 2.7, \gamma_{\text{Cu}} = 1.4$.\(^{(37)}\)

The EQCM has revealed several interesting features in UPD processes that otherwise would be difficult to detect. For example, in the aforementioned investigations with bismuth, it was discovered that a precipitous increase in electrochemical charge accompanied the third UPD peak, with a slight decrease in mass (Figure 8). This behavior may be associated with the loss of electrolyte ions that are adsorbed during the first two UPD events. More detailed studies of Pb UPD on Au and Ag revealed behavior that demonstrated the importance of the underlying substrate in UPD processes.\(^{(38-40)}\)

Whereas Pd UPD on Au electrodes in borate buffer was accompanied by a mass increase, UPD on Ag electrodes exhibited a mass decrease due to the desorption of $\text{BO}_2^-$ ligands from a previously adsorbed anionic Pb(II) species. The adsorption of the latter was detected by the frequency decrease upon addition of Pb(II) to the electrolyte solution prior to electrochemical experiments. The data reflected the desorption of three $\text{BO}_2^-$ ions per adsorbed Pb(II) species during the UPD process. These studies clearly reveal the value of the EQCM in probing electrode surface processes, providing information critical to complete understanding of rather complicated mechanistic schemes.

The EQCM has also enabled determination of the electrovalency numbers for anion adsorption. Simultaneous measurement of electrochemical charge and frequency during anodic adsorption of $\text{Br}^-$ and $\text{I}^-$ under conditions where monolayer coverage previously had been demonstrated revealed $\gamma_{\text{Br}} = -0.39 \pm 0.03$ and $\gamma_{\text{I}} = -1.01 \pm 0.03$.\(^{(41)}\) These studies indicate that, while adsorption of iodide occurs with complete charge transfer, bromide ions partially retain their negative charge.

The capabilities of the EQCM provide a unique approach for examining electrochemical dissolution, which is important in processes such as corrosion and electrochemical machining. While EQCM studies of dissolution have been rather limited, these reports indicate that important mechanistic information can be obtained readily with this method. For example, EQCM investigations of the anodic dissolution of nickel films revealed two maxima in the $\Delta f$ versus potential plots, indicating a potential-dependent dissolution of the $\alpha$ and $\beta$ phases of NiH$_x$.\(^{(42)}\) Analysis of the frequency changes and electrochemical charge in EQCM studies of the anodic dissolution of a nickel–phosphorus film revealed that two different Ni–P compositions were present in the film prior to dissolution. This was consistent with the known Ni–P phase diagram.\(^{(43)}\)

EQCM studies of the electrochemical dissolution of copper films in oxygenated sulfuric acid revealed that the dissolution rate was linearly dependent upon $[\text{O}_2]$ and $[\text{H}^+]$, enabling the authors to conclude that a heterogeneous surface reaction was operative.\(^{(44)}\)

Several groups have demonstrated that the EQCM is also an ideal method for examining the electrochemically induced adsorption of hydrogen and deuterium in metal films such as palladium.\(^{(45-47)}\) Such studies can have significant impact on understanding the commercially important isotopic separation of H and D. In addition

Figure 9 (a) Frequency shift versus time for a 366.6-nm thick Pd film on an AT-cut quartz resonator in 0.1-M LiOH/H$_2$O. The numbered arrows indicate the potential applied to the film: (1) 0.00 V; (2) $E$ scanned to and held at $-1.14$ V; (3) $E$ scanned to and held at $-1.27$ V; (4) $E$ scanned to and held at 0.0 V. The frequency decrease is larger than that expected based on the mass of the cathodic hydrogen absorption process, and is attributed to compressive stress in the Pd film upon hydrogen absorption which increases the frequency. (b) Frequency shift versus time for a 475-nm thick Pd film on an AT-cut quartz resonator in 0.1-M LiOH/D$_2$O. The numbered arrows indicate the potential applied to the film: (1) 0.00 V; (2) $E$ scanned to and held at $-1.20$ V; (3) $E$ scanned to and held at 0.0 V. The frequency decrease is smaller than that expected based on the mass of the cathodic deuterium absorption process, and is attributed to compressive stress in the Pd film upon deuterium absorption which increases the frequency. (Reproduced from Cheek and O’Grady, *J. Electroanal. Chem.*\(^{(45)}\) Copyright (1990) with permission from Elsevier Science.)
to measurement of H/D adsorption, these EQCM studies have revealed the important role of stress in EQCM measurements. Cheek and O’Grady reported a rather novel approach to this issue by using a “double resonator” technique that previously had been reported for measuring stresses in Si films resulting from ion implantation (in vacuum). This method involves the comparison of frequency responses from palladium-coated AT-cut and BT-cut quartz crystals during electrochemically induced ingress and egress of H or D (Figure 9). Both crystals have identical sensitivities to mass changes, but a compressive stress in a film on an AT-cut crystal results in a frequency decrease while an identical stress in a film on a BT-cut crystal results in an increase in frequency of similar magnitude. The amount of stress can be determined by Equation (11),

\[
S = (K^{\text{AT}} - K^{\text{BT}}) \left( \frac{\Delta f^{\text{AT}}}{f_0^{\text{AT}}} - \frac{\Delta f^{\text{BT}}}{f_0^{\text{BT}}} \right) \tag{11}
\]

where \(K^{\text{AT}}\) and \(K^{\text{BT}}\) are the stress coefficients for the different resonators \((K^{\text{AT}} = 2.75 \times 10^{-12} \, \text{cm}^2 \, \text{dyn}^{-1} \) and \(K^{\text{BT}} = -2.65 \times 10^{-12} \, \text{cm}^2 \, \text{dyn}^{-1}\)). Stress in thin films is manifested in a stress in the quartz crystal, which is tantamount to a change in the elastic modulus, \(\mu\). Because the acoustic velocity depends upon this quantity, these stresses result in changes in the resonant frequency (this effect is similar to tightening a violin string to increase the frequency of vibration). Thus, hydrogen adsorption in a Pd film on an AT-cut crystal gave a frequency decrease that was much larger than expected, indicating compressive stresses in the Pd film upon H adsorption, \(-351\) Hz for a 367-nm thick Pd film, compared to \(-185\) Hz expected for the mass change due to H adsorption. However, the same experiment on a BT-cut crystal resulted in a very small increase in frequency, \(+20\) Hz for a 475 nm thick Pd film.

### 3.5 Electrochemical Quartz Crystal Microbalance Investigations of Thin-film Growth

The EQCM provides an extremely useful approach to the in situ study of the nucleation and growth of a wide variety of thin films on electrodes, ranging from oxide films to molecular solids and monolayers. In principle, the ability to measure mass and electrochemical current simultaneously allows determination of chemical stoichiometries, Faradaic efficiencies, and reaction kinetics. The EQCM therefore complements current transient methods typically used to study nucleation and growth, providing information which otherwise cannot be obtained readily. The time constant for EQCM measurements (see above) is within the timescale of many electrochemical processes.

The growth of metal-oxide films has been investigated at copper and gold electrodes, the EQCM enabling determination of the stoichiometry of the oxides formed. In addition, these studies revealed frequency responses that were consistent with morphological changes of the electrode surface accompanying oxide formation. This resulted in much larger changes in the frequency during oxide growth that was attributed to surface roughening.

![Figure 10](image-url)
and subsequent trapping of water in the cavities of the roughened surface. The surface roughness was retained initially after reduction of the oxide back to the metal, but the frequency gradually returned to its original value, indicating dynamic changes in the morphology of the roughened metal electrodes (Figure 10). In addition to providing valuable mechanistic insight into oxide growth, these studies illustrate the sensitivity of the EQCM to surface roughness effects.

EQCM studies of the electrochemical deposition of molecular films have also been studied. The adsorption of surfactants containing redox-active ferrocene (Fc) groups (referred to as C$_{12}$ and C$_{14}$, which designates the length of the alkyl chain) could be induced electrochemically, because adsorption occurred when these species were in the reduced (Fc$^{0}$) state (Figure 11).$^{50,51}$ Upon oxidation to the oxidized form (Fc$^{+}$), the surfactants rapidly desorbed. Interestingly, the desorption rate was dependent upon the chain length of the surfactant. Whereas short-chain-length surfactants resulted in rapid desorption following electrochemical oxidation, the EQCM frequency changes indicated that long-chain surfactants desorbed much more slowly following oxidation. Mechanistic and thermodynamic information for these films was thereby attainable.\(^{(52)}\)

The nucleation, growth, and dissolution of thicker films of related species, namely diheptyl viologen, was also examined with the EQCM. Examination of these processes at different potentials provided insight into the nucleation behavior of this system.\(^{(53)}\)

The EQCM has also been useful in the investigation of the nucleation and growth of “electronic” materials. For example, the deposition of thin semiconductor films was examined, and the rather complicated mechanism involved in the deposition of thin films of Te was determined by comparison of the EQCM frequency changes and electrochemical charge.\(^{(54)}\) Similarly, the electrodeposition of B-doped $\beta$-PbO$_2$ thin films was studied with the EQCM and details of the film composition and

![Figure 11](image.png)
catalytic activity toward oxygen atom transfer reactions were realized.\textsuperscript{(55)}

The growth and redox chemistry of Prussian blue and related films has been examined by EQCM, with particular attention paid to the degree of solvation of these films and the ion transport during electrochemical cycling. These studies would be expected to have an impact on the use of these films in sensors and electrochromic displays. The initial EQCM study of Prussian blue films found that the frequency decrease during electrochemical deposition was consistent with a high degree of hydration.\textsuperscript{(56)} Subsequent EQCM studies of these films revealed that cation transport accompanied changes in the redox state during potential cycling, although at low pH conditions proton transport was also involved. Ion and solvent transport in related nickel ferrocyanide films during potential cycling in 0.1-M CsCl solutions also has been examined. The results were consistent with transport of Cs\textsuperscript{+} ions upon change in the redox state of the film.\textsuperscript{(57)} The mass change calculated from the Sauerbrey equation, Equation (2), which assumes rigid-layer behavior, suggested that H\textsubscript{2}O was expelled from the film as Cs\textsuperscript{+} was incorporated during reduction. This was verified by a clever experiment in which the process was studied in H\textsubscript{2}O and D\textsubscript{2}O; the mass change associated with the solvent was found to increase by 10\% in D\textsubscript{2}O. This verified the participation of solvent and provided corroborative evidence of rigid-layer behavior.

The Prussian blue and nickel ferrocyanide films consist of a low density pseudocrystalline lattice in which the metal atoms are organized by cyanide ligand bridges between octahedral metal centers. As a result, metal ion intercalation into the interstices in the lattice is affected by the size and hydration of the cation. The different amount of work required for intercalation of the different ions is manifested as a dependence of the formal potential of the films on the identity and concentration of the metal ion in the supporting electrolyte. Analysis of EQCM data acquired during redox cycling of Prussian blue films in propylene carbonate containing different relative amounts of NaClO\textsubscript{4} and LiClO\textsubscript{4} revealed that intercalation of Na\textsuperscript{+} was favored over Li\textsuperscript{+} by a factor of 15.\textsuperscript{(58)} This capability was demonstrated to be useful for the analytical identification of metal ions in a flow injection mode.\textsuperscript{(59)} Simultaneous electrochemical and EQCM measurements were performed in which the Prussian blue film was held at a potential known to be selective for a given cation, and the charge and mass changes associated with ion transport were measured. Comparison of the charge and mass changes enabled determination of the molar mass and, therefore, identification of the cation.

The electrodeposition of polymer films has also been investigated with the EQCM, in particular the electrodeposition of poly(vinylferrocene) (PVF) films.\textsuperscript{(60)} These studies indicated that in oxidative electrodeposition of PVF in CH\textsubscript{2}Cl\textsubscript{2}, initially more polymer was deposited than expected based on the deposition of one monomer unit per electron. It was suggested that during the initial stages partially oxidized polymer was deposited (i.e. large Faradaic efficiencies), possibly with solvent or electrolyte trapped in the polymer. However, the results indicated that the total frequency change was smaller than that expected for the amount of charge passed during the deposition. This apparent loss of mass sensitivity suggests, as with some of the examples above, that the deposited film is not ideally rigid.

### 3.6 Electrochemically Active Polymer Films

Without a doubt, the EQCM has found its most extensive use in the investigation of electrochemically active polymer films, including redox and conducting polymers. Indeed, to a large extent it was the first report of an EQCM study of polypyrrole films by Kaufman et al. that heightened interest in the EQCM method.\textsuperscript{(61)} The benefits of the EQCM were immediately obvious, as it became clear that the identity of the counterions exchanging between the films and electrolyte could be determined. In addition, the amount of solvent accompanying ion exchange could be determined by calculating the mass in excess of that expected from the electrochemical charge. Since these initial studies, numerous polymer films have been investigated with the EQCM and many mechanistic and thermodynamic insights into their behavior have been realized. The practitioner should be cautious when using the EQCM with polymer films, as changes in the viscoelasticity of the films are not uncommon when ion population and solvent swelling are involved.

The corresponding changes in viscoelasticity can result in dramatic frequency changes which are unrelated to mass changes. In many cases, this warrants experimental verification that rigid-layer behavior is present over the thickness and composition ranges examined. This can be accomplished by performing experiments with different polymer thicknesses over a reasonable range and by using impedance analysis to elucidate the contribution from changes in mechanical properties. If these factors are taken into account, the EQCM can be an especially valuable tool in examining electrochemically active polymer films.

It is reasonable to claim that PVF is ubiquitous in the subdiscipline of polymer-modified electrodes. Similarly, it has been among the polymer films most extensively examined with the EQCM. One of the initial investigations involved measurement of the frequency changes associated with ion transport required for electroneutrality...
and the amount of solvent accompanying ion transport in PVF films.\(^{(62)}\) Based on a frequency decrease that accompanied oxidation of the PVF film, it was determined that ClO\(_4^-\) and PF\(_6^-\) were inserted without accompanying solvent, with one equivalent of anions inserted for each equivalent of electrons (Figure 12). The process was reversible, as evidenced by the frequency increase upon electrochemical reduction. Electrochemical oxidation of PVF films in the presence of other counterions, however, occurred with varying amounts of solvent incorporation, with the amount of incorporated water per ion decreasing in the order Cl\(^-\) > IO\(_3^-\) > BrO\(_3^-\) > ClO\(_3^-\) \(\approx\) NO\(_3^-\) > CH\(_3\)-C\(_6\)H\(_4\)-SO\(_3^-\) \((0.5)\).\(^{(63)}\) Indeed, crosslinking of the PVF film was necessary to prevent its dissolution upon oxidation. Unfortunately, determination of the amount of incorporated solvent is not feasible in the case of Cl\(^-\) or IO\(_3^-\) because of the dramatic changes in viscoelasticity that accompany the large degree of swelling when these ions are present. On the other hand, solvent incorporation for the other ions could be measured reliably (the amount of solvent incorporated per counterion are indicated above within the parentheses). The EQCM has been employed to investigate transport in redox polymer films such as PVF and poly(thionine) of mobile neutral species such as water, particularly with regard to thermodynamic changes in solvent activity in the polymer film and transport kinetics.\(^{(64–66)}\) These studies indicate that the number of solvent molecules per counterion need not be integral, and that it is feasible that neutral ion pairs are also involved in the transport. Comparison of EQCM frequency changes at different scan rates also revealed that mass changes and electrochemical charge changes do not always occur simultaneously.\(^{(67,68)}\) That is, counterion motion to maintain electroneutrality during redox changes must always be established, but global equilibrium may lag behind. In particular, these studies revealed that electroneutrality would be achieved initially during redox by using counterions already present in the film, followed by transport of ions from the solution. Similar behavior was observed for redox-active poly(nitrostyrene) films.\(^{(69)}\) The behavior has been attributed to potential gradients within the film that affect ion transport, and to the low dielectric constant of the film.\(^{(70–72)}\) In the case of poly(thionine) experiments, comparison of current transients following a series of potential steps, suggested that transport of different species occurs on different timescales (Figure 13).\(^{(73)}\) It was surmised that proton transport necessary to achieve electroneutrality was rapid, but that global equilibrium occurred more slowly by transport of the neutral ion pair H\(_2\)O\(^+\)ClO\(_4^-\) and H\(_2\)O. These conclusions were supported by experiments performed in D\(_2\)O, which exhibited trends consistent with the difference in mass of H and D. These results have important consequences in the design and synthesis of polymer films in applications where charging and discharging rates are critical, for example in sensors or energy storage.

EQCM studies revealed that ion transport into PVF films upon oxidation was slower than their transport out of the film during reduction.\(^{(74)}\) This is presumably because of the change in density accompanying the swelling of the oxidized film. It was estimated that in the first oxidation cycle of electrochemically deposited PVF films, water uptake began only after the film was approximately 40% oxidized and that 50% of the water was retained after subsequent reduction.\(^{(75)}\) Water transport in following cycles was reversible, apparently

ELECTROANALYTICAL METHODS

Figure 13: Transient mass changes following the application of a potential step from −0.1 V to +0.5 V (vs SCE) to a poly(thionine) film in HClO₄ solution. (a) Solvent in H₂O, pH = 1.6; (b) Solvent is D₂O, pD = 2.1. The potential step converts a fully reduced film to a fully oxidized film at long times. The pH and pD values were adjusted to achieve near zero net mass change at long times after switching. Mass increases upwards. The same polymer film was used in H₂O and D₂O. Note that the initial mass change is larger than that after global equilibrium is achieved at longer times. (Reproduced by permission of the Electrochemical Society, Inc. from Bruckenstein et al. 73)

Figure 14: Frequency response of a PVF film in the presence of 5-mM KI₃ and 1.0-M KNO₃. The right hand ordinate refers to the number of equivalents of I incorporated into the film normalized to the amount of PVF coverage on the piezoelectrically active area (0.28 cm²). [PVF]₀ = 4.1 × 10⁻⁶ equiv. cm⁻². (Reproduced with permission from Ward. 17 Copyright (1988) American Chemical Society.)

with some water always retained in the polymer film. Transport in PVF films can also be severely affected by the nature of the counterion. For example, EQCM studies indicated that ion exchange of ferro- or ferricyanide into PVF during electrochemical cycling resulted in irreversible incorporation of Fe(CN)₆³⁻/⁴⁻ in the film. 76 This process led to a slow decrease in the electroactivity of the film, presumably due to an electrostatic “crosslinking” by the multiply charged ion that inhibited further transport of Fe(CN)₆³⁻/⁴⁻. It should be noted that variability in these results may be expected in different laboratories because of differences in film preparation.

The EQCM can also be used to examine the kinetics of chemical reactions of solution species with redox polymer films. The chemical oxidation of a PVF film by KI₃ was monitored by measurement of the frequency decrease associated with insertion of the I₃⁻ counterion following oxidation (Figure 14). These experiments were possible because the PVF film could be held in its reduced form prior to the chemical reaction in the presence of the oxidant by holding the potential of the electrode negative of E⁰ (PVF/PVF⁺). This established the initial conditions for this measurement. The results yielded the stoichiometry of the reaction (1 equivalent I₃⁻ per PVF⁺ formed) as well as the pseudo-first-order rate constant for the reaction.

3.7 Electrochemical Quartz Crystal Microbalance Investigations of Conducting Polymers

Interest in the EQCM method heightened considerably after it was reported in the investigation of polypyrrole films. 61 Since that time, numerous reports have appeared describing attempts to deconvolute the typically complicated behavior involved in the preparation of conducting polymer films and their subsequent doping behavior. The value of the EQCM was immediately evident in those initial polypyrrole studies in which it was determined that reduction of electrochemically (by oxidation of pyrrole in LiClO₄) prepared polypyrrole films resulted in Li⁺ insertion to maintain electroneutrality rather than expulsion of ClO₄⁻. This behavior was attributed to strong...
Figure 15 (a) Cyclic voltammetry data for a polypyrrole film immobilized on an EQCM in 1.0-M LiClO$_4$/THF, presented as $dQ/dV$ versus $V$. Oxidation occurs at peaks A and B while reduction occurs at C and D. (inset shows $V$ vs $Q$) (b) EQCM data presented as $df/dV$ versus $V$ showing differential mass changes associated with the oxidation and reduction features in (a). The up arrow ($\uparrow$) indicates increasing mass and the down arrow indicates decreasing mass. (Reproduced with permission from Varineau and Buttry.\textsuperscript{62} Copyright (1987) American Chemical Society.) (c) EQCM response upon oxidation of a polypyrrole film followed by reduction in tetraethylammonium tosylate electrolyte. The polypyrrole film was prepared by electrochemical oxidation of pyrrole. (d) EQCM response upon oxidation of a polypyrrole-co-[3-(pyrrol-1-yl)propanesulfonate] film followed by reduction in tetraethylammonium tosylate electrolyte. In both cases, the increase in frequency upon oxidation and decrease in frequency upon reduction are associated with transport of cations. (Reproduced with permission from Kaufman et al.\textsuperscript{61} \textit{Phys. Rev. Lett.}, Copyright (1984) by the American Physical Society.)

It was also discovered that subsequent cycling of these films in the presence of $n$-Bu$_4$N$^+$p-CH$_3$C$_6$H$_4$-$SO_3^-$ resulted in frequency changes consistent with anion insertion during the oxidative doping step, with its expulsion during reduction (Figure 15). This behavior clearly revealed that the nature of ion transport in conducting polymers was strongly dependent upon the nature of the counterions. The impact of this behavior on the design of energy storage systems with regard to weight, power density, and energy density prompted several other EQCM investigations of conducting polymers, including poly(pyrrole), poly(aniline), and poly(thiophene). Decreasing the mass of the transport species would lead to higher energy densities, whereas higher power densities would be realized by faster transport rates.

Poly(pyrrole) film growth was also examined with the EQCM. It was concluded that film deposition involved the initial formation of soluble oligomers, which upon further polymerization precipitated on the electrode. EQCM frequency changes that corresponded to the mass of deposited polypyrrole revealed
a second-order dependence of the electropolymerization rate on pyrrole concentration, suggesting the bimolecular coupling of oxidatively formed radical cations was involved in the rate determining step. Subsequent EQCM studies of poly(pyrrrole) revealed more details of the ion transport and its dependence upon film preparation. Electropolymerization of pyrrole in the presence of large polymeric anions such as poly(4-styrenesulfonate) and poly(vinylsulfonate) resulted in films whose transport properties differed significantly from films prepared in the presence of more conventional anions. In these studies, conventionally prepared films exhibited frequency changes during doping–undoping cycles that indicated anion transport for ClO$_4^-$, BF$_4^-$, or PF$_6^-$ ions. However, in electrolytes containing poly(4-styrenesulfonate) mixed transport of both poly(4-styrenesulfonate) anions and cations was observed in conventionally prepared films. If the films prepared in poly(4-styrenesulfonate) were used, then the transport during doping–undoping was completely dominated by the cation of the support electrolyte. Cation transport also dominated in the doping–undoping cycles of self-doped conducting copolymers. 

Anion transport for ClO$_4^-$, BF$_4^-$, or PF$_6^-$ ions on the electrode surface and functional groups on the protein. Recent efforts have further demonstrated the utility of the EQCM in the characterization of electrode processes involving biologically relevant species. The adsorption of organosulfur reagents, followed by alternate electrostatic adsorption of ferrocene-modified poly(allylamine) and anionic glucose oxidase was monitored with the QCM in order to quantify the amount of redox-active material deposited on the gold electrode after each step. Impedance analysis was employed to characterize viscoelastic contributions from the poly(allylamine) polymer solution in contact with the EQCM. Viscoelastic contributions were also observed during the deposition of the glucose oxidase layer, although at long times these effects vanished so that the Sauerbrey approximation could be used reliably. The ability to measure the amount of material deposited in each step was important for elucidation of the electrochemical properties of these films. In a similar manner, the EQCM was employed to quantify the amount of electroactive and nonelectroactive protein in multilayer films prepared by alternate deposition of film layers. 

The EQCM data reflected a linear increase of film mass with increasing number of layers. 

The adsorption of flavin adenine dinucleotide (FAD) on the gold electrode of the EQCM revealed deposition of FAD upon reduction and its reversible desorption upon oxidation. The voltammetric adsorption and desorption of cysteine at the gold electrode of an EQCM has been examined. Cysteine was adsorbed following cathodic reduction of the surface gold oxide, but the EQCM data indicated that the apparent surface mass upon reduction was less when cysteine was present than in solutions without cysteine. This was attributed to a decrease in surface hydration accompanying the loss of the oxide and adsorption of cysteine.
The adsorption of green fibrous polymeric products formed by reaction of electrochemically generated dications of the carotenoid (7E,7Z)-diphenyl-7,7'-diapocarotene was monitored with the EQCM. Coulometric measurements performed during cyclic voltammetry, combined with the EQCM measurement of the amount of polymer adsorbed, enabled determination of the average molar mass per electron (5400 g mol\(^{-1}\) electrons).\(^{94}\)

4 IMPEDANCE ANALYSIS METHODS

Impedance analysis is being used increasingly to evaluate the contributions from viscous and viscoelastic effects associated with films on the quartz resonator. There is not sufficient space in this article to give a detailed explanation of this approach, but it can be described briefly as a technique in which a voltage within a specified range of frequencies is broadcast across the quartz crystal and the current measured. The impedance or admittance is measured, and the Butterworth–van Dyke (BVD) equivalent circuit parameters determined by numerical fitting of the data. The mechanical properties corresponding to the electrical parameters can then be assessed. Commercially available impedance analyzers allow a complete set of parameters to be measured within 1 min, enabling dynamic measurements, albeit on a rather slow timescale.

Quartz crystals are electromechanical devices, and therefore their mechanical vibrations can be described in terms of electrical equivalents.\(^{95}\) This also serves to enhance understanding of the EQCM, particularly the conditions under which the Sauerbrey equation, Equation (2), is valid. The quartz resonator can be described according to a mechanical model with elements of mass, compliance (the ability of an object to yield elastically under an applied force), and friction. The electrical equivalent of this system is an electrical circuit that has an inductor, a capacitor, and a resistor connected in series (Figure 16). In this equivalent circuit, the inductor, \(L_1\), represents the mass displaced during oscillation, \(C_1\) the energy stored during oscillation (the compliance is the inverse of the elastic, or Hooke's constant), and \(R_1\) the energy dissipation due to losses that are tantamount to internal friction. In order to describe the quartz crystal behavior accurately, a parallel capacitance must also be included that represents the static capacitance of the quartz plate with its electrodes and any stray parasitic capacitances. The complete circuit is commonly referred to as the BVD circuit.\(^{96,97}\) The series branch of the circuit is referred to as the motional branch since it reflects the vibrational behavior of the crystal.

\[ \frac{1}{Q} = \frac{1}{Q_0} + \frac{1}{Q_1} \]

\[ Q_0 = \frac{2\pi f_0}{f_1} \]

\[ Q_1 = \frac{2\pi f_1}{f_2} \]

\[ f_0 = \frac{1}{2\pi \sqrt{LC}} \]

\[ f_1 = \frac{1}{2\pi \sqrt{LC + RL}} \]

\[ f_2 = \frac{1}{2\pi \sqrt{LC + RL + RC}} \]

Figure 16 (a) BVD equivalent electrical circuit used to describe the mechanical properties of a quartz resonator. The components \(L_1, C_1\) and \(R_1\) in the motional branch of the circuit represent the inertial mass, compliance, and energy dissipation in the crystal, and \(C_0\) represents the static capacitance of the quartz crystal. (b) Equivalent electrical circuit used to describe the mechanical properties of a quartz resonator immersed in a liquid. The inductance \(L_2\) and resistance \(R_2\) represent the mass and viscosity components of the liquid.

The relationship between this circuit and the quartz crystal is especially useful because the \(L\) \(C\) \(R\) branch is identical to a “tank circuit”, in which oscillations can be sustained by cycling of current between the capacitor and the inductor. When the capacitor in this circuit discharges through the inductor, a magnetic field is established around the inductor as it opposes the current. When the capacitor discharge is complete and the current falls to zero, the electromotive force in the inductor creates a current in the direction opposite to the original current and the capacitor recharges. Repetition of this cycle results in electrical oscillation, with the oscillations dampened by an amount proportional to \(R\). In the case of quartz crystals, the \(R\) values are rather small and sustained oscillations are favored.

As a result of the electromechanical relationship between quartz crystals and electrical circuits, the equations of harmonic motion of the quartz crystals are closely related in form to the expressions describing the properties of the \(L\) \(C\) \(R\) tank circuit. This has been reviewed elsewhere\(^{13}\) and a detailed description is not given here. The equivalent electrical parameters in terms of crystal properties are given in Equations (12–15), along with typical experimental values for these parameters. In these relationships, \(D_0\) is the dielectric constant of quartz, \(\varepsilon_0\) the permittivity of free space, \(r\) a dissipation coefficient corresponding to the energy losses during oscillation, \(\varepsilon\) the piezoelectric stress constant and \(c\) the elastic constant. Note that while \(L_1, C_1,\) and \(R_1\) depend upon \(\varepsilon, C_0\) does not participate directly in piezoelectricity. It should also be noted that \(L_1\) depends upon the density; in fact, the
Figure 17 Admittance analysis data for 5-MHz and 30-MHz quartz resonators in aqueous media. The increased capacitance of the thinner 30-MHz resonator lifts the admittance circle upward along the imaginary susceptance ($jB$) axis, but the decreased resistance associated with the decreased crystal thickness increases the diameter of the admittance circle. The latter effect is critical as it compensates for the capacitance effect such that the admittance circle crosses the real axis, which is required for establishing resonance. The admittance data was collected with a Hewlett Packard Model 4194A Impedance Analyzer. (Reproduced with permission from Lin et al.,© Copyright (1993) American Chemical Society.)

The use of impedance analysis, or its inverse admittance analysis, for characterization of crystal properties and performance can be demonstrated by the rather simple comparison of the admittance plots for 5-MHz and 30-MHz quartz crystals mentioned above (Figure 17). The smaller thickness of the 30-MHz quartz crystal leads to an increase in $C_0$ and the expected shift of the admittance locus upwards on the admittance plot (by an amount equal to $wC_0$). This increases the likelihood that the admittance locus will not cross the real axis. Under this condition, operation of the EQCM at its resonant frequency using a feedback-mode oscillator, which relies on maintaining a frequency at zero phase angle, can be difficult. The smaller area of the electrode overlap for the 30-MHz resonators somewhat diminishes this effect. More important, the 30-MHz resonators have smaller

quantity $t_3$ that is equivalent to the mass per unit area in the Sauerbrey equation. These equivalent representations provide a quantitative approach to examining the properties of the EQCM, the role of the liquid environment and thin films on the resonant frequency response, and the design of quartz resonators.

$$C_0 = \frac{D_{06}A}{\iota_0} \approx 10^{-12} \text{ F}$$  \hspace{1cm} (12)

$$C_1 = \frac{8A\varepsilon^2}{\pi^2\iota_0 c} \approx 10^{-14} \text{ F}$$  \hspace{1cm} (13)

$$R_1 = \frac{t_3 A}{8A\varepsilon^2} \approx 100 \Omega$$  \hspace{1cm} (14)

$$L_1 = \frac{t_3 \rho}{8A\varepsilon^2} \approx 0.075 \text{ H}$$  \hspace{1cm} (15)
values of $R_1$ and $L_1$, owing to the smaller thickness of these crystals compared to their lower frequency counterparts. The decrease in $R_1$ is evident from the 30-MHz crystal admittance locus, which is significantly larger than the 5-MHz locus. The admittance locus crosses the real axis for both resonators, but the conductance value of the series resonant frequency $f_s$, where the locus crosses the real axis, is larger for the 30-MHz resonator. Because EQCM experiments using a feedback-mode oscillator operate at $f_s$, the quartz crystals can be operated with lower loss in liquid media or in air than the more commonly used 5-MHz crystals.

While the BVD circuit accurately describes the operation of the QCM in vacuum or the gas phase, it is not a sufficient description when the QCM or EQCM is used in liquids where the liquid density and viscosity alter the resonator characteristics. The density of the liquid effectively adds to the mass of the resonator, while its viscosity provides additional energy damping. The effect of a Newtonian liquid can be described by adding an additional inductance and resistance $L_2$ and $R_2$ in series with the motional branch of the BVD circuit, in which $L_2$ and $R_2$ are related to the extra mass of the liquid and its viscosity, respectively (Figure 17). (88)

Our laboratory devised a method based on an electromechanical model that relates the electrical parameters to the mechanical characteristics of a composite resonator consisting of a $AT$-cut thickness shear mode quartz crystal and a viscoelastic polymer film. The theoretical component of this method is based on a previously reported relationship Equation (16), (89) where $\mu_F$ is the film shear modulus (or equivalently, the storage modulus $G'$), $\mu_F$ is the complex film shear modulus, $\eta_F$ is the film viscosity (or equivalently, the loss modulus-frequency quotient $G''/\omega$), $\rho_{F}$ is the film density, $L_F$ is the film thickness, $\rho_Q$ is the quartz density, $w$ is the angular frequency $(w = 2\pi f)$, $f_Q$ is the quartz thickness, $A_{ACT}$ is the piezoelectric active area, $\varepsilon_{22}$ is the quartz dielectric constant, $\varepsilon_{26}$ is the quartz piezoelectric constant, $c_{66}$ is the quartz shear modulus, $\tilde{c}_{66}$ is the complex quartz shear modulus, $\eta_Q$ is the quartz viscosity, and $Y$ is the complex resonant admittance.

$$\begin{align*}
Y = & \frac{\frac{i\omega A_{ACT} \varepsilon_{22}}{f_Q}}{\frac{\rho_{Q} c_{66} \sin(k_{Q} f_Q)}{k_{Q}} + k_{F} \tilde{\mu}_{F} \tan(k_{F} L_{F}) \cos(k_{Q} f_Q)} + k_{F} \tilde{\mu}_{F} \tan(k_{F} L_{F}) \cos(k_{Q} f_Q) - \frac{2c_{26}^{2}}{f_{Q} \varepsilon_{22}} \\
& \times 1 - \cos(k_{Q} f_Q) + \frac{k_{F} \tilde{\mu}_{F}}{2k_{Q} c_{66}}\tan(k_{F} L_{F}) \sin(k_{Q} f_Q)
\end{align*}$$

(16)

where

$$k_{Q} = w\sqrt{\frac{\rho_{Q}}{c_{66}}} = w\sqrt{\frac{\rho_{Q}}{c_{66} + \frac{\varepsilon_{26}^{2}}{\varepsilon_{22}} + i\omega \eta_{Q}}}$$

and

$$k_{F} = w\frac{\rho_{F}}{\tilde{\mu}_{F}} = w\sqrt{\frac{\rho_{F}}{\mu_{F} + i\omega \eta_{F}}}$$

This electromechanical equation is derived from linear equations of motion relating the electrical admittance and the mechanical properties of a composite resonator. An algorithm based on this relationship was limited to measurement of the mechanical properties of polymer films containing various amounts of solvent that affected the viscoelastic properties. These measurements require somewhat cumbersome and time-consuming numerical analysis during measurement that inhibits the use of complete impedance analysis techniques in EQCM applications. (100–102) Even direct impedance analysis requires long analysis times because the measurement involves sweeping a range of frequencies to evaluate the resonator conductance and numerically fit the data to obtain the BVD parameters. Consequently, experimental strategies based on impedance analysis have not been used extensively in EQCM applications. However, changes in $R$ can be rapidly inferred from changes in the amplitude of the voltage output of the oscillator during operation with a conventional feedback oscillator.

5 EMERGING METHODS

Several modifications of the quartz microbalance have appeared in which the oscillation is induced by electrodes that are near, but not in contact with the quartz surface. (103–107) These resonators, which can be referred to as electrode-separated quartz crystal resonators, allow examination of interfacial processes occurring directly on the quartz surface or on other films deposited on the quartz. The capabilities of these methods have been extended to a scanning configuration in which the position of a small conducting probe, serving as one of the excitation electrodes, is controlled by computer-activated positioning of the sample stage. (106) In principle, this procedure enables qualitative mapping of the mass distribution and viscoelastic properties of films on the quartz resonator. Two configurations have actually been demonstrated. In an “overscanning” mode the conducting probe is scanned over the upper surface, onto which a film of interest has been deposited, and the bottom surface has the conventional metal electrode.
covering a large region of the crystal. An alternative “underscanning” mode relies on the conducting probe scanning the lower surface of the quartz crystal while the upper surface is coated conventionally with the large area excitation electrode. Both configurations allow introduction of an electrochemical working electrode. In the overscanning mode the working electrode is independent of the excitation electrodes, whereas in the underscanning mode the excitation and working electrode are the same.

The format of the EQCM is amenable to combination with other in situ techniques. This was illustrated for the SEM/EQCM experiments described earlier in this article. This capability is further demonstrated by ellipsometric studies of the nucleation and growth of poly(aniline) films performed in conjunction with the EQCM.\textsuperscript{109,110}

which allowed complete characterization of the polymer films (Figure 18). Whereas the EQCM provided the total mass of the deposit, ellipsometry provided the thickness. Accordingly, the combination of these techniques allows determination of the density, which is not realized by either technique alone. The major conclusions of these studies were that the kinetics for growth of the poly(aniline) films depended upon the electrochemical conditions, and that self-assembled monolayers of aniline derivatives on the electrode surface promoted nucleation and films with higher densities.

6 SUMMARY

The increasing use of the EQCM and the examples described in this article demonstrate the power of this method in elucidating the fundamental interfacial processes occurring at electrode surfaces. The rather simple concept and low cost of the equipment necessary to perform EQCM experiments should encourage physical, analytical, and electrochemists to use this technique routinely in the laboratory. Although numerous laboratories use the EQCM regularly, the contributions of interfacial slip, stress, surface roughness, viscosity, viscoelasticity, and influence of the liquid phase to propagation of the acoustic energy are difficult to quantify. The new practitioner (and even experienced ones) should expend some effort to grasp the basic principles of EQCM operation in order to avoid pitfalls and misinterpretations that can occur if these effects are ignored. Generally, verification of ideal behavior is possible through fairly simple experiments, as discussed in this article, or through more sophisticated impedance analysis techniques. It is anticipated that as the EQCM becomes more widely appreciated and used, many of these effects will be better understood. Nevertheless, the EQCM is well within the reach of most electrochemical laboratories and properly used can provide details of electrode processes that were previously unattainable.

In this article, various electrochemical methods used in neuronal cell studies are examined. Electrochemical methods useful for investigating neuronal communication directly in the brain and in ex vivo brain slices are discussed. Additionally, we describe how voltammetric methods can be used to make intracellular and extracellular measurements at single cells. Technical aspects of each method are emphasized and selected applications are highlighted.

Although techniques such as electron microscopy and patch clamp can be used to visualize and monitor cellular events, electrochemical methods can provide chemical information about neurotransmitters being released and transported in brain tissue or even at single cells. The main competing technique for in vivo measurements of neurotransmitters is microdialysis. Although microdialysis coupled to separation techniques can be more selective and more sensitive than electrochemical methods, the latter methods are considerably faster and more accurate in determining the in vivo concentration. At single cells, electrochemistry provides extremely small probes compared to microdialysis thus facilitating measurements of single-cell events. Here, again, the response time associated with electrochemical methods is important for measurements of millisecond exocytosis events.

Electrochemical methods are clearly a powerful means to measure rapid changes in neurotransmitters that are electroactive and found in tissue or cellular microenvironments.

1 INTRODUCTION

The study of the brain and its function has been an area of research for many years. Analytical techniques have provided unique information regarding the neurophysiology and neuropharmacology of the brain. One technique, electroanalysis, has found extensive applications since many neurochemicals are easily oxidized or reduced. Electroanalytical techniques possess unique characteristics that make them useful for studying chemical processes occurring in complex biological matrices. Attributes that are particularly advantageous include the ability to provide qualitative and quantitative information for electroactive substances in the brain.

The fundamental building block of the brain is the single nerve cell or neuron. It has been estimated that the human brain contains $10^{10}$ to $10^{12}$ neurons. Nerve cells are unique in that they are specialized to communicate with each other. A typical neuron is comprised of a cell body, dendrites and an axon (Figure 1). According to the classical model of neurotransmission, neuronal signals are received at the dendrites, integrated at the cell body, and then sent down the axon to the terminal where they are relayed to the next cell or cells. The site of information transfer between two cells is called the synapse. This structure is essentially a very small gap between cells which ranges in size from 1 to 100 nanometers.

2 OVERVIEW OF ELECTROCHEMICAL METHODS

2.1 Potentiometric Compared with Voltammetric Measurements

Potentiometry and voltammetry are two of the basic electroanalysis methods available for chemical analysis. These are broad categories that include many different techniques developed for use in different experimental situations. Potentiometric ion-selective electrodes (ISEs) are commonly used to measure concentrations of ions both outside and inside cells. The most common ISEs...
are used to measure pH, K⁺, Na⁺, or Ca²⁺ levels in resting and stimulated cells. These types of electrodes have been used to study diffusion characteristics as well as to determine the volume of the extracellular space in the brain. Although potentiometric methods can be used to study ion fluxes and concentrations, these techniques are not capable of detecting neurotransmitters at neuronal cells. For these types of measurements, voltammetry must be employed.

Several neuroactive species are easily oxidized (Figure 3) and are therefore amenable to detection by voltammetry. The current created by the oxidation of these species in response to an applied voltage is the primary operating principle behind the various voltammetric techniques. Voltammetric techniques can be put into one of two broad categories: potential step (or pulse) and continuously applied potentials. The pulse techniques include chronoamperometry, normal pulse voltammetry, and differential pulse voltammetry, while linear sweep voltammetry, cyclic voltammetry, and amperometry can be categorized as continuous potential methods. A comparison of the various electrochemical methods reveals that each method has specific advantages and disadvantages in particular protocols. Generally, the voltammetric method used depends on the needs of the user.

### 2.2 Electrode Types

Platinum wire and carbon fibers are just two of the many materials that have been used in the construction of microelectrodes. Both platinum and carbon can be fabricated into durable electrodes with micron or smaller size tips and used in minute environments. Platinum and carbon have also been combined to construct platinized carbon microelectrodes. Selectivity, sensitivity, stability, and reproducibility of the signals are the major differences between these two types of electrodes, especially when working in biological environments such as the brain or with cells in culture. The electrode material of choice for a given experiment depends upon the nature of the substance(s) being investigated.

#### 2.2.1 Micro Platinum Electrodes

Platinum possesses partially unsaturated surface d-orbitals which facilitate the adsorption stabilization of free radical products in slow electrooxidation reactions and are beneficial in the detection of aliphatic alcohols and amines. Platinum electrodes are also very sensitive to the presence of hydrogen and oxygen. This is advantageous if one wishes to detect H₂ or O₂, but is detrimental if these gases are background signals that obscure detection of the analyte. The strong adsorption characteristics of Pt makes it useful in a “clean” environment, but much less so in biological matrices where proteins and other biological molecules can adsorb to the surface. Ultimately, electrode fouling decreases the sensitivity, stability, and reproducibility of the measurements. These issues have been addressed by depositing thin layers of platinum on carbon surfaces as well as by coating the platinum with various permselective membranes. Although these modifications have improved the performance of platinum electrodes, there is still room for further improvements.

#### 2.2.2 Carbon-fiber Electrodes

Owing to their resistance to drift and inert nature in biological environments, carbon fibers have been used to develop carbon-fiber microelectrodes with dimensions in the micrometer range. The small size of these electrodes provides many advantages in terms of electrochemistry and the practical aspects of their use in biological environments. The improved faradaic to nonfaradaic current ratio at microelectrodes compared to macroelectrodes, for example, enhances the signal-to-noise ratio. Additionally, currents generated at microelectrodes typically lie in the picoampere to nanoampere range. Such small currents facilitate the use of simpler two-electrode configurations in voltammetric studies. In terms of the biological environment, the smaller currents also mean fewer products are generated at the electrode. This is beneficial since many of these products are detrimental to cells at high concentrations. Small currents...
created at microelectrodes are not as disruptive to normal cellular function and are less likely to interfere with the normal activity of the surrounding tissue or cells.\(^{22}\)

Like platinum, some adsorption of large biomolecules does occur on carbon-fiber electrodes\(^ {23}\) causing the electrode’s response to deteriorate over time. Usually there is a 30–50% decrease in electrode sensitivity following implantation into brain tissue. This decrease levels off after approximately two hours and reproducible, stable measurements can be collected for six to twelve hours.\(^ {21,24,25,26}\) In culture, sensitivity loss is much less.\(^ {18}\) In both instances, the decrease in electrode sensitivity requires that electrodes be calibrated after experiments.

3 IN VIVO VOLTAMMETRY

3.1 Introduction

The brain is a chemically heterogeneous organ with a fluid environment containing various chemical substances at different concentrations that can change on the second to millisecond timescale. An ideal technology to investigate the neurochemistry of the brain should be able to sample from spatially discrete locations without perturbing the local neuronal environment and have the sensitivity and selectivity to detect and discriminate between chemicals that are present at a wide range of concentrations. This technology should also be able to make measurements on a timescale similar to that on which neuronal signaling occurs. Over the last three decades, two methods have been developed which are complementary to each other and collectively satisfy these requirements. These methods are microdialysis and in vivo voltammetry.

3.2 Microdialysis Compared with In Vivo Voltammetry

In vivo voltammetry and microdialysis sampling have played a large role in detecting neurotransmitter release and turnover. For both these techniques, stereotaxic coordinates are used to implant the sensors into a specific region of the brain. Probes for microdialysis consist of two concentric tubes. The tips of these probes are covered with a low-molecular-weight cut-off dialysis membrane. Small molecules are removed from the extracellular fluid (ECF) by diffusing across this membrane. Fluid containing the analytes is pumped through the probe and out of the brain for subsequent analysis. High-performance liquid chromatography (HPLC) can be used to simultaneously detect many analytes in the dialysis samples. The combination of a sample volume requirement of microliters for HPLC and slow diffusion of molecules across the dialysis membrane results in sampling rates that are generally five to ten minutes, although this has been pushed into the range of a few seconds in recent years.\(^ {27,28}\)

Voltammetry permits measurements to be made more rapidly by applying a small potential to an electrode and measuring the current resulting from the oxidation of electroactive species. In contrast to microdialysis, voltammetric techniques analyze the sample at the surface of the probe. The rate at which molecules can be detected is limited only by diffusion and the response time of the electrode. Another distinction between in vivo voltammetry and microdialysis is the small size of the recording electrodes used in voltammetry. Most electrodes used in vivo have a 10–20 µm total tip diameter. This is approximately ten times smaller than the outer diameter of a microdialysis probe. The size of both types of probes is large compared to cells and synapses. As a result, measurements obtained from both of these techniques reflect the dynamics of chemical events occurring in the extracellular space of the brain. However, the smaller electrochemical probes make it possible to get closer to the synaptic region while minimizing damage to the surrounding brain tissue.

The fast acquisition rates and small size of voltammetric probes allow more rapid and spatially discrete measurements of chemical dynamics. Although microdialysis, in contrast, is better suited to monitor concentration changes for a wider dynamic range of compounds at low levels over prolonged periods of time, the temporal and spatial resolution of this technique are not as good as for voltammetry at microelectrodes.

Since its inception, in vivo voltammetry has been used to measure the dynamic changes of many different substances in the brain that could be considered “informational”. One goal which has driven the development of this technology has been to measure directly, in real time, changes in the concentration of neurotransmitter(s) that result from neural activity. Throughout this section of the article, key developments that have helped to push this technology toward this goal will be highlighted and findings from select studies using in vivo voltammetry will be discussed.

3.3 Development of In Vivo Voltammetry to Detect Stimulated Neurotransmitter Release

3.3.1 Selectivity of In Vivo Voltammetry

In vivo voltammetry is a general term used to describe a group of loosely related electrochemical techniques developed to measure electroactive compounds in the brain. These techniques can vary with the type of scanning method (i.e. pulse or continuous), the rate at which they scan, and the type of electrode used. As a result of these different experimental approaches, each technique varies in selectivity, rate of data acquisition, and sensitivity.
Although it is not the intent here to compare the merits of every technique, (this has been done elsewhere)\(^\text{21,29}\) in general, the voltammetric method used depends on the needs of the user. Despite the varied approaches, one of the main disadvantages of using voltammetry is its limited selectivity. The lack of chemical selectivity in voltammetric techniques results mainly from the fact that electrodes respond to any substance that can be electrolyzed at the applied potential.

Initial studies reporting the voltammetric detection of neurotransmitters in the rat brain attributed the increase in oxidation current following intraperitoneal (i.p.) amphetamine injection to an increase in the catecholamine dopamine.\(^\text{30,31}\) Gonon et al. later exploited the ability of electrochemically modified electrodes to clearly resolve ascorbic acid and dihydroxyphenylacetic acid (DOPAC) to provide evidence that ascorbic acid, not dopamine, was responsible for the increased electrochemical signal observed following administration of amphetamine.\(^\text{32}\) Using an electrode that could discriminate between ascorbic acid, dopamine, and DOPAC, investigators from Wightman’s laboratory also concluded that ascorbic acid increased in the ECF of the brain following amphetamine injection.\(^\text{33,34}\) The conclusions from these in vivo voltammetry studies were later independently confirmed using push–pull perfusion and microdialysis methods. Using the superior selectivity of HPLC, Salamone et al. showed that ascorbic acid increases in concentration in response to amphetamine.\(^\text{35}\) It should be noted that further technical developments did make it possible to detect the amphetamine-induced release of dopamine using voltammetry (see below). Additionally, voltammetry continues to be a very useful method for following changes in ECF levels of ascorbic acid in vivo.\(^\text{36,37}\)

Ascorbic acid and DOPAC are both electroactive and are always present in ECF at concentrations 10^6 to 10^7 greater than biogenic amines. Detecting these neurotransmitters in the presence of ascorbic acid and metabolites such as DOPAC therefore remains an analytical challenge. Another way to enhance the selectivity of voltammetric electrodes is to coat the electrode with a permeation selective film. Nafion™ is a sulphonated polymer that is selectively permeable to cations, but repels anions. When coated onto the tip of an electrode, Nafion™ permits cations such as dopamine and serotonin to reach the electrode surface, but rejects anions such as ascorbic acid and DOPAC. Thus, the development of electrodes coated with Nafion™\(^\text{38}\) has been a critical component of selective measurements with in vivo voltammetry.

### 3.3.2 Fast Compared with Slow Voltammetric Methods

By utilizing the above techniques to improve selectivity, several investigators have been able to successfully demonstrate that neurotransmitters can be directly detected in the brain using voltammetry. However, exocytosis occurs on a millisecond timescale. In these early examples, data was acquired on the second to minute timescale.\(^\text{32,33,39}\) Therefore, these relatively slower voltammetric methods were not capable of detecting faster signals that could have been present. The merits of fast and slow in vivo voltammetric methods have been reviewed elsewhere.\(^\text{40}\) In general, slower voltammetric methods, and microdialysis, are best suited to monitor slow changes in concentration of metabolites and related species that result from pharmacological or behavioral stimuli.\(^\text{41}\) However, these types of changes are slow and long lasting (minutes to hours) compared to release processes and do not require that high-resolution sampling methods be used. Furthermore, changes in metabolite levels do not reliably reflect release of the parent neurotransmitter.\(^\text{42,43}\)

To accurately measure neurotransmitter dynamics following direct rapid stimulation of nerve terminals, voltammetric methods need to acquire data on a sub-second timescale. Owing to their high rate of data acquisition, chronoamperometry and fast cyclic voltammetry (FCV) are both well suited to measure the acute kinetic characteristics of release processes in “real time”. Before the advent of very small electrodes, which facilitated faster scanning methods, the most popular voltammetric methods for rapid electrochemical measurements were potential step techniques such as chronoamperometry.\(^\text{5}\)

For typical chronoamperometry, data acquisition usually requires 50 to 100 ms. Compared to pulse techniques, however, scanning methods provide a higher degree of selectivity and are more effective at discriminating possible interferents (see below). Data for an entire FCV can be acquired in about 10 to 15 ms using a scan rate of 300 V s\(^{-1}\). Since small carbon-fiber microelectrodes can be used in combination with FCV, this method provides excellent temporal and spatial resolution. Consequently, FCV has been the most widely utilized electrochemical technique for in vivo voltammetry. In the following sections, issues related to the selectivity and sensitivity of in vivo voltammetry will be discussed with an emphasis on FCV.

### 3.3.3 Selectivity of Fast Cyclic Voltammetry

There are two ways FCV provides selectivity. FCV at microelectrodes is dominated by double-layer charging current which masks the faradaic current arising from the oxidation–reduction of electroactive neurotransmitters. This background current can be digitally subtracted from the faradaic current to give a “background subtracted” voltammogram. During periods between stimulation, the majority of the FCV signal is presumably due to the
detection of ascorbic acid. Since individual fast cyclic voltammograms are obtained on a timescale similar to release processes, following neuronal stimulation, neurotransmitters are the most likely compounds to change during the time of each scan. Metabolite and ascorbic acid concentrations should change on a much slower timescale.

Generally, the shape of background corrected voltammograms vary with different chemical species. At the fast scan rates used in FCV, voltammogram shapes are kinetically controlled. As a result, most electroactive analytes in the ECF have a unique “fingerprint” which can be used to tentatively identify what has changed in concentration during the time course of the scan. Unfortunately, qualitative chemical analysis cannot be solely based on the shape of the voltammogram. The neurotransmitters serotonin, epinephrine, and dopamine for example, all oxidize at potentials between +0.2 and 0.5 V against Ag–AgCl with untreated electrodes, and the shape of the signal from these compounds is not always readily distinguishable. Additionally, interpreting the shape of the voltammogram can become complicated if more than one neurotransmitter changes in concentration. When using FCV to detect electroactive neurotransmitters in the brain, it is essential that independent neuropharmacological interventions be used to verify the identity of the detected neurotransmitter.\(^{41,44}\)

3.3.4 Sensitivity of In Vivo Voltammetry

Realizing the limited sensitivity of voltammetric methods in general, Ewing et al.\(^ {33}\) used elevated levels of K\(^ +\) to stimulate massive amounts of dopamine release (Figure 4). This method of stimulation increased ECF levels of dopamine from basal levels of approximately 5–10 nanomolar to the low micromolar range. Although a relatively slower method of voltammetry (normal pulse voltammetry) was used, these results demonstrated that, with an adequate stimulus, voltammetry could be used to monitor the stimulated release of dopamine.

Owing to the limited spatial and temporal control provided by elevated levels of K\(^ +\), this method of stimulation was later replaced by the use of a bipolar stimulating electrode.\(^ {45}\) Stimulating electrodes can be used to artificially trigger action potentials within a specific group of neurons. Stimulating and recording electrodes can be placed in different locations in the brain of an animal during an experiment. For example, with the working electrode in the terminal field where release occurs, the stimulating electrode could be placed in the cell body region, along ascending fiber tracts, or directly in the terminal fields to stimulate release. Despite these options, most workers stimulate ascending pathways. One approach that has been used extensively

\[ \text{Figure 4} \text{ Electrochemical response to injection at 0 time of 0.6 \mu \text{mol of potassium chloride in 1.0 \mu L of physiological buffer into the caudate nucleus. Distance from electrode to syringe tip is 0.8 mm. (a) Current vs time response at 0.5 V. Solid line, injection of physiological buffer only; points, injection of potassium chloride. (b) Difference voltammograms. Solid lines, dopamine (25 \mu M) and ascorbic acid (200 \mu M) in pH 7.4 buffer after in vivo use; circles, in vivo result from subtracting voltammograms obtained at the circles shown in (a). Current scales: } i_{\text{DA}} = 25 \text{ pA, dopamine; } i_{\text{AA}} = 28 \text{ pA, ascorbic acid; and } i_{\text{in vivo}} = 22 \text{ pA, in vivo. (Reproduced from Brain Research, A.G. is to electrically stimulate the medial forebrain bundle (MFB) while detecting dopamine concentration changes in the rat striatum with a carbon-fiber electrode.
3.4 Fast Cyclic Voltammetry and Electrical Stimulation: Applications In Vivo

Combined, the use of local electrical stimulation and FCV make it possible to directly measure, in real time, changes in the concentration of neurotransmitter(s) that result from neural activity. Stamford et al. were the first to realize the advantages of combining these two techniques and, since then, FCV and electrical stimulation have been the most widely used methods for examining the dynamics of electroactive neurotransmitters in vivo and in vitro (see below). Detailed and exhaustive discussion of the neurochemistry examined in all of these studies is beyond the scope of this article. However, selected findings are discussed here to illustrate the utility of this methodology.

Kuhr and Wightman have used fast-scan voltammetry at Nafion-coated, beveled, carbon-disk electrodes with electrical stimulation of the rat MFB to monitor the time course of stimulated dopamine release in the caudate nucleus. The maximum concentration of dopamine detected at a single electrode location during stimulation has been found to be directly proportional to the frequency of pulses in the stimulation train. Dopamine is observed in the ECF for approximately 1.5 s when short stimulation times are employed demonstrating the brief time that detectable dopamine levels are present following stimulation. The disappearance of dopamine appears to occur exponentially, which is characteristic of first-order uptake kinetics. Using the uptake inhibitor, nomifensine, a large increase in current is observed when cells are stimulated with a small electrical stimulus (15 pulses in 250 ms), which normally gives only a barely detectable signal (Figure 5). These results confirm the large effect that uptake has on the detected dopamine signal in vivo.

In another example, in vivo voltammetry has been used to suggest that the brain is not “hard-wired” meaning that some neurons communicate by pathways outside of the synapse. Garris et al. have used FCV with Nafion-coated, beveled, disk electrodes and electrical stimulation to examine dopamine efflux from the synaptic junction. It has been determined that binding of released dopamine to receptors and uptake sites does not appreciably alter the diffusion of dopamine from the synaptic cleft in the rat nucleus accumbens. This implies that the dopamine synapse is designed for efficient transmitter efflux from the synaptic cleft so that dopamine can escape the synapse and affect a greater number of cells. This proposed scheme contrasts with the established model of neurotransmission derived from experiments at the neuromuscular junction where communication occurs only inside the synapse (Figure 6).

The simultaneous detection of two neurochemically relevant substances in vivo has also been accomplished using FCV. Zimmerman and Wightman have demonstrated that both dopamine and O₂ can be independently and simultaneously monitored at a single
Nafion™-coated disk electrode by scanning from 0.0 V to +0.8 V followed by a cathodic sweep to −1.4 V before returning to a resting potential of 0.0 V. Several laboratories have also used voltammetry at carbon-fiber electrodes, in combination with other techniques, to simultaneously acquire electrochemical and electrophysiological information in vivo and in vitro.\(^{22,50,51}\) In one particular study, Ewing et al. used carbon-fiber microelectrodes combined with tungsten microelectrodes to simultaneously measure the effects of d-amphetamine and ascorbic acid on the electrochemical and unit activity of neostriatal neurons.\(^{22}\) Neurotransmitter efflux and unit activity may be considered respectively as indices of presynaptic and postsynaptic neuronal function. The ability to record both of these phenomena makes it possible to correlate the release of neurotransmitter from a discrete population of release sites with changes in neuronal activity at a specific region in the brain.\(^{51}\)

### 4 VOLTAMMETRY IN BRAIN SLICES

#### 4.1 Introduction: Use of Brain Slices Compared with In Vivo Techniques

The first report of voltammetric techniques being used in combination with brain slices described experiments that were designed to shed light on data obtained in vivo.\(^{52}\) Owing to the many technical advantages of using this approach, slice-voltammetry methods have become very popular and have nicely complemented work done in vivo. For these types of experiments, voltammetry is performed in slices of brain tissue that are created by taking “sections” from a whole brain. This approach has several advantages that make it attractive. It avoids any potential confounding effects that may arise from the use of anesthetics and inherently reduces/simplifies the complexities of the neuronal circuits present during an experiment. Additionally, when using brain slices one does not need to worry about the ability of a given agent to cross the blood brain barrier or the possible toxic side effects that an agent may have on the whole animal. Combined, these two factors widen the range of agents which can be investigated. Since the investigator can control the composition of the fluid perfusing the tissue, it is also possible to minimize potential interferents such as ascorbic acid.

#### 4.2 Technical Issues

##### 4.2.1 Slice Preparation

In general, when slices of brain tissue are prepared for an experiment, the brain is quickly removed from an animal and immediately placed in chilled physiological saline. A block of tissue containing the desired region of the brain is then isolated from the whole brain and slices of tissue are created by sectioning this block using a vibratome. A slice is then placed into a tissue bath where the tissue has complete access to the physiological buffer. In the bath, the tissue is continuously superfused with warm physiological buffer saturated with oxygen and carbon dioxide (32–37°C; some investigators have reported that the temperature of the slice affects the long-term stability of the electrochemical signal\(^{51}\)). Slices are usually cut to a thickness of 150–400 µm and the physiological buffer is flowed through the bath at a rate of approximately 0.25–1 mL min\(^{-1}\). The dimensions of the slice allow oxygen to easily diffuse into the tissue and the constant exposure to fresh buffer helps to establish a metabolically stable system.\(^{53}\) Once situated within the tissue bath, the slice is allowed to incubate for 30 to 60 minutes prior to an experiment. This allows the preparation to stabilize and equilibrate with its surrounding environment.

##### 4.2.2 Experimental Set-up

With the aid of a dissecting microscope, the working electrode is lowered into the slice, using a micro-manipulator, to a position of 75 to 100 µm below the surface of the tissue. This ensures that the whole sensing area of the electrode is completely enclosed within the slice. Auxiliary and reference electrodes are placed in convenient positions within the tissue bath. While solutions of elevated K\(^+\) have been used to stimulate neurotransmitter release in slice-voltammetry experiments,\(^{54}\) as with experiments in vivo, the most popular method used in slices has been electrical stimulation. This type of stimulation is accomplished by placing a bipolar stimulating electrode in or on the slice approximately 100 to 400 µm away from the working electrode. The stimulating electrodes can be accurately placed, with the aid of the microscope, at a specific region within the slice. Interestingly, the relative efficacy of this method of stimulation varies with the area of the brain being studied. Single pulse stimulations (0.1 ms width, 20 V) for example, consistently elicit detectable levels of dopamine in slices of rat striatum\(^ {55}\) while trains of stimuli (i.e. 25 pulses, 50 Hz, 0.1 ms, 20 V) are required to give similar voltammetric signals for serotonin in slices of rat dorsal raphe or suprachiasmatic nuclei.\(^{56}\) For a more detailed discussion of the technical issues concerning the use of voltammetry in brain slices, the reader is referred to an excellent review by Stamford et al.\(^ {57}\)

#### 4.3 Applications

Although FCV is not the only voltammetric technique that has been used with slices,\(^ {58,59}\) it is the method...
NEUROTRANSMITTERS, ELECTROCHEMICAL DETECTION OF

Figure 7 Typical recordings of electrically stimulated dopamine efflux in striatal slices from DAT +/+ , DAT +/− and DAT −/− mice. DAT +/+ represents mice with both alleles of the DAT; DAT +/− represents mice missing one allele; DAT −/− represents mice missing both alleles. A single biphasic electrical pulse (4 ms, 350 µA) was applied at the time indicated by the arrows with a locally placed bipolar electrode. Data points (open circles) were collected from a recording electrode every 100 ms. Inset shows cyclic voltammograms recorded at the peak of dopamine efflux in each slice. Voltammograms recorded from DAT +/+ (solid line), DAT +/− (broken line) and DAT −/− (dotted line) mice were scaled to approximately the same peak amplitude for comparison. These cyclic voltammograms are not significantly different from those obtained with authentic dopamine. Measurements were made in at least 22 slices from at least 5 animals for each group. The average time to clear released dopamine was 1, 3, and 100 s in DAT +/+ , DAT +/− and DAT −/−, respectively. (Reproduced from ref. 67. © 1996 with permission from Nature.)

that has been most widely applied to these preparations. Since voltammetry was first used in slices, there have been a variety of experiments performed using different voltammetric techniques. The focus of the majority of these studies can be loosely categorized as: examining neurotransmitter release and uptake in different regions of the brain, comparing neurotransmitter release and uptake between different regions of the brain, and investigating the presynaptic regulation of neurotransmitter release by pharmacologically manipulating autoreceptors. Recent studies have even used voltammetry in slices to better understand the physiological mechanisms regulating ischaemia-induced dopamine release. Since it is beyond the scope of this article to cover in detail all the findings from these studies, we have chosen to illustrate the utility of using voltammetry in slices by focusing on work recently done in brain slices from mice lacking the DAT gene. Voltammetry experiments in slices from mice lacking the DAT have shown that disruption of the DAT significantly increases the time required for dopamine to be cleared from the ECF. Indeed, when both alleles of the DAT are disrupted, dopamine remains in the ECF up to 100 times longer than normal (Figure 7). These results directly demonstrate that the DAT is critically involved in regulating dopamine ECF levels, and hence dopamine signaling, and provide a biochemical basis for the spontaneous hyperactivity observed in DAT knockout mice.

Subsequent experiments in slices from DAT knockout mice have taken advantage of the unique genetic background of these animals to help unravel the complex actions of the psychostimulant amphetamine. Amphetamine can cause the release of dopamine from neurons in a manner which is impulse independent and has little calcium dependence. The neurochemical mechanism responsible for the releasing action of amphetamine is attributed to both the drug's ability to redistribute dopamine from secretory vesicles and its ability to cause the release of cytoplasmic dopamine into the ECF via the DAT (a process that has been called reverse transport). The relative importance of these two mechanisms in the releasing action of amphetamine, however, has been controversial.

Figure 8 shows how amphetamine affects the electrically stimulated and baseline levels of dopamine when applied to striatal slices from wild-type (DAT +/+ ,
control) and DAT knockout (DAT −/−) mice. As shown in Figure 8, approximately 10 min after amphetamine is applied to slices from wild-type mice there is a distinct rise in baseline dopamine levels. At the same time, as can be seen by the decrease in height of the sharp ‘spikes’ of dopamine efflux, amphetamine also decreases the amount of electrically stimulated dopamine release. Approximately 25 min after the drug has been administered, the steady increase in the baseline reaches a plateau. In contrast to these results, when amphetamine is applied to slices from DAT −/− mice, although there is also a decrease in the stimulated efflux of dopamine, no change in baseline dopamine levels are observed. These results directly demonstrate that the DAT is required for the releasing action of amphetamine.

To examine vesicle depletion and its effect on reverse transport independently, slices from control and DAT deficient mice were exposed to the vesicle depleting agent Ro4-1284. As can be seen in Figure 9, this drug, like amphetamine, caused a gradual reduction in the stimulated release of dopamine. Unlike amphetamine however, Ro4-1284 did not cause an increase in baseline dopamine levels. When amphetamine was applied to slices from wild-type mice, after Ro4-1284 had completely blocked stimulated dopamine release, there was a rapid increase in baseline dopamine levels that reached values similar to those observed when amphetamine was used alone. The rate of this increase, however, was much faster with baseline concentrations of dopamine reaching their maximum values 5 to 10 min after the application of amphetamine.

From these two sets of experiments it has been estimated that it takes approximately 25 min for amphetamine to exert its depleting action on synaptic vesicles and only 5 min for amphetamine to release cytoplasmic dopamine via reverse transport. These results demonstrate that both vesicular depletion and reverse transport play central roles in the releasing action of amphetamine. However, vesicle depletion appears to be the rate-limiting step.

5 INTRACELLULAR VOLTAMMETRY AT SINGLE CELLS

5.1 Overview

The ability to detect species inside single nerve cells is very important in order to gain further insight into the metabolism, function and regulation of individual

![Figure 8](image)
neurons. Electrode tips 10 µm or less in diameter are small enough to impale fairly large cells (100–200 µm diam.) without causing excessive damage or interfering with cellular function. The development of carbon and platinum microelectrodes with total overall dimensions in the micron range has made it possible to directly detect several different electroactive substances in the cytoplasm of single nerve cells.\(^{14,70,71}\)

Initial intracellular voltammetric studies, conducted by Meulmans et al.\(^{14}\) to measure the endogenous ascorbic acid levels in single *Aplysia* neurons, demonstrated the potential of electrochemical methods to intracellularly monitor electroactive neurochemicals. Using 0.5- to 2-µm tip diameter carbon-fiber or platinum electrodes in combination with differential pulse voltammetry, it has been determined that the endogenous ascorbic acid concentration in these single neurons is approximately 100 µM. Similar approaches have also been used to monitor the kinetics of uptake, clearance of two electroactive drugs,\(^{72}\) and levels of serotonin in single *Aplysia* neurons.\(^{14}\)

Development of glucose microsensors has provided the ability to qualitatively monitor glucose transients in the cytoplasm of a single cell. Glucose metabolism is of particular interest because glucose is a major energy source for the brain.\(^{16}\) Abe et al.\(^{73,74}\) have used 2-µm diameter platinized-carbon ring electrodes with amperometric detection (0.6 V versus SSCE (sodium saturated calomel electrode)) to monitor intentional manipulations of cytoplasmic glucose in the giant dopamine cell of the pond snail *Planorbis corneus*. Intracellular oxygen levels in the giant dopamine cell of *Planorbis* have also been measured using Nafion\(^{18}\)-coated platinized-carbon ring electrodes with differential pulse voltammetry.\(^{16}\) In the following section, experiments investigating intracellular dopamine in the giant dopamine cell of *Planorbis* will be described.

### 5.2 Monitoring Intracellular Dopamine

Carbon and platinum microelectrodes and various electrochemical techniques have been used to monitor...
dopamine inside the giant dopamine cell from the pond snail *Planorbis corneus*. Active transport of dopamine into the cell has been monitored using linear scan voltammetry and poly(ester sulfonic acid)-coated carbon ring electrodes. In these experiments, the electrode is implanted in the neuron and the cell is bathed in 0.5 mM dopamine.\(^{70}\) When the oxidation current at the electrode is monitored at +0.78 V and plotted against time, distinct peaks can be seen following extracellular application of the dopamine solution (Figure 10). The rising portion of each peak represents the active transport of dopamine across the cell membrane, and the decreasing portion of each peak represents the clearance of cytoplasmic dopamine through metabolism and/or vesicularization.

In these experiments, the peak current for repeated bathings with dopamine gradually decreases over time. The average loss of response in the cell is 36% after 20 min of continuous voltammetry. This loss is most likely due to a decrease in electrode sensitivity brought on by specific adsorption of large biomolecules. Loss of sensitivity from fouling of the electrode surface has been largely overcome by use of integrated pulse linear scan voltammetry, at platinized-carbon ring electrodes.\(^{17}\) This method, also referred to as pulsed amperometric detection (PAD), minimizes electrode fouling while maintaining a reactive electrode surface. The applied waveform, based on the pulse techniques developed by Johnson’s group,\(^{75,76}\) consists of a rapid cyclic potential sweep followed by a large positive potential pulse to oxidatively clean the electrode surface and then a large negative potential pulse to restore the reactivity of the electrode.\(^{17}\) This technique allows continuous amperometric detection that is both sensitive and reproducible. The average peak concentration of dopamine uptake in the *Planorbis* studies has been found to be 44 ± 2 µM, and the average rate of dopamine clearance, estimated from the linear portion of the declining limiting current, is 0.29 µM s\(^{-1}\).\(^{17}\)

To gain insight into the distribution of dopamine inside the cell, intracellular studies measuring basal dopamine levels have also been carried out. Carbon ring electrodes with electrode tips of approximately 6 µm have been placed inside the giant dopamine cell of *Planorbis* to monitor dopamine using staircase voltammetry.\(^{71}\) Basal levels of free dopamine are below the detection limit of this method, so 0.5 mM dopamine is added extracellularly. The uptake of dopamine by the cell causes a sharp increase in the oxidation current detected in the cytoplasm, results in agreement with those presented by Lau et al.\(^{17,70}\) The extracellular application of nomifensine (700 µL, 0.6 mM), an uptake inhibitor, diminishes the oxidation current, verifying that the rise in current observed is due to the uptake of extracellular dopamine and not free intracellular dopamine.

Bathing the cell in 300 µL of 50% ethanol disrupts the cellular membranes and results in a large increase in intracellular dopamine. Capillary electrophoresis has been used to verify the identification of the electroactive compound released upon ethanol exposure. In the resting state, cytoplasmic dopamine levels are below the detection limits of this method. However, upon exposure to ethanol, 14 fmol of dopamine is detected. Assuming an injection volume of 100 to 300 pL, the

---

**Figure 10** Observed time course plot of repeated dopamine bathings (0.5 mM, 30 µL each arrow) with the electrode placed in the cell body of the identified dopamine neuron of *Planorbis corneus*. The dopamine solution used for extracellular bathings was a modified snail saline solution. The current was monitored at +0.78 V vs SSCE with 7 s between measurements. (Reproduced from ref. 70. © 1991 with permission from Wiley-VCH.)
cytoplasmic dopamine concentration following ethanol treatment is approximately 1.4 × 10^{-4} to 4.7 × 10^{-5} M.\(^{(71)}\) This technique has also been coupled to off-column amperometric detection\(^{(77)}\) with a detection limit of 10^{-8} M in 50 pL samples.\(^{(78)}\) These lower detection limits are necessary for detection of basal levels of cytoplasmic free dopamine. Olefirowicz and Ewing\(^{(78)}\) have determined basal dopamine concentration in Planorbis to be 2.2 ± 0.5 μM.

6 EXTRACELLULAR VOLTAMMETRY AT SINGLE CELLS

6.1 Introduction

As described above, carbon-fiber microelectrodes have been used in a number of studies to monitor extracellular changes in neurotransmitter levels both in the brain and in brain slices. One limitation to these types of studies is that the observed signal arises from multiple cells. Furthermore, since the electrodes are much larger than the synapse, one can only infer what is going on at the site of neurotransmitter release. The next frontier for voltammetry has been to monitor the exocytotic release of neurotransmitters at the level of a single cell.

Several different examples are given below illustrating how carbon-fiber microelectrodes can be used to monitor exocytosis at a single cell. In all examples the experimental protocols are similar. In most cases, with the exception of two examples, tissue containing the cell(s) of interest is dissociated into a single-cell suspension and cultured. The distance between single cells in culture facilitates electrode placement onto a cell and minimizes possible interferences from neighboring cells. Carbon-fiber microelectrodes, which are usually beveled for these experiments, are positioned via a micromanipulator next to or directly against a single cell (see Figure 11). To stimulate exocytosis, nanoliter volumes of a chemical stimulant (i.e. elevated K\(^+\) and/or nicotine) are administered to a cell via pressure injection through a micropipette placed approximately 20–30 μm from the cell. The electrode is held at a constant potential and the current is sampled at high rates. This electrochemical technique is referred to as amperometry. When electroactive neurotransmitters are released from a cell and approach the electrode surface they are oxidized. The resulting current gives rise to a positive deviation in the baseline.

6.2 Overview of Systems Used for Single-cell Analysis

Single-cell amperometry has been used to investigate many types of cells that release easily oxidized substances by exocytosis. Some of the nonsynaptic cell systems that have been investigated include bovine adrenal chromaffin cells, rat pheochromocytoma (PC12) cells, beige mouse mast cells, and human pancreatic β-cells. Synaptic systems including invertebrate and mammalian neurons have also been investigated. A brief overview of some of the key studies using these different cell types will be presented in the following sections.

6.2.1 Bovine Adrenal Chromaffin Cells

The direct measurement of catecholamine secretion from a single cell was first reported by workers in Wightman’s laboratory.\(^{(79)}\) Bovine adrenal chromaffin cells were used in this study. Adrenal chromaffin cells are useful models of neurotransmitter biosynthesis, metabolism, and secretion owing to their neuroectodermal origin and biochemical and functional similarities with postganglionic sympathetic neurons.\(^{(80)}\) Changes in the chemistry surrounding a single chromaffin cell are monitored using FCV at an electrode placed next to a cell. The application of 100 μM nicotine results in a series of sharp irregular concentration spikes superimposed on a secretion envelope (Figure 12d). Individual cyclic voltammograms confirm that the substances secreted and detected are catecholamines (Figure 12b). The secretion of catecholamines at a single cell has been shown to be induced by stimulants such as nicotine, the nicotinic agonist carbachololine, and K\(^+\).\(^{(81)}\) Furthermore, K\(^+\)- and nicotine-stimulated secretion could be inhibited by Cd\(^{2+}\), a calcium channel blocker, while nicotine-stimulated secretion could be selectively inhibited by hexamethonium, a sympathetic ganglionic blocker.\(^{(81)}\)

Many of these observations of catecholamine secretion are consistent with similar measurements made at multiple-cell preparations such as the intact adrenal
Figure 12 Cyclic voltammetric response (200 V s\(^{-1}\), repeated at 100-ms intervals) of a carbon-fiber electrode to norepinephrine ejection from an adjacent micropipette and to catecholamine secretion from a single chromaffin cell. Panels (a) and (b) are averaged background-subtracted voltammograms of the substances whose concentration changed during the measurement interval of panels (c) and (d). Each time point in panels c and d is the integrated current recorded from 0.5–0.6 V from individual voltammograms (hatched lines in panels (a) and (b)); bars to the right in panels (c) and (d) are the conversion of current to catecholamine concentration based on calibration curves constructed with standards. Panels (a) and (c) are the electrode response to a 1-s ejection (3 nL) of 20 µM norepinephrine applied at \(t = 0\) with the ejection pipette 20 µm from the electrode. Panels (b) and (d) are the electrochemical response obtained with the electrode tip adjacent to a single cell; at \(t = 0\), a 1-s ejection of nicotine (100 µM) was made 20 µm away from the cell. (Reproduced with permission from ref. 79. © 1990 The American Society for Biochemistry.)

gland, adrenal slices, and whole cultures of adrenal cells. Additionally, since vesicular fusion events should result in discrete packets of catecholamines being released from the cell surface, the observed chemical concentration spikes are the expected consequence of exocytosis.

Combined, the above evidence suggested that the single-cell electrochemical signals were the result of secretion of catecholamines via exocytosis. To improve the temporal resolution of the measurements made with FCV and to more accurately measure exocytosis, which can occur on the millisecond to microsecond timescale, single-cell measurements have been made in the amperometric mode. The faster sampling rates possible with this technique make it possible to more clearly resolve the chemical spikes. For each spike, the integrated current, or charge, is proportional to the mass of the analyte detected and can be used in Faraday’s law, Equation (1), to calculate the number of molecules detected per each spike event. Faraday’s law can be expressed as

\[
\frac{Q}{nF} = N
\]  
(1)
where $Q$ is the charge in coulombs, $n$ is the number of moles of electrons transferred per mole of analyte oxidized, $F$ is the Faraday constant (96,485 C equiv$^{-1}$) and $N$ is the total number of moles of substance oxidized.

Several results from the above studies have demonstrated that the properties of the electrochemically detected spikes at single bovine adrenal cells correlated well with expectations based on the exocytotic secretion of catecholamines from individual vesicles. For example, cyclic voltammograms at individual concentration spikes confirm that the spikes are due to the detection of concentration packets of catecholamines rather than an electrical artifact.\(^{(79,81)}\) Additionally, in agreement with the requirements of Ca$^{2+}$ for exocytosis, spikes do not occur in the absence of this ion.\(^{(80)}\) Within each vesicle there is a discrete or quantal amount of neurotransmitter. If each of the observed chemical spikes was due to the exocytotic release of neurotransmitter(s) from a single vesicle, the amount detected per each spike event should be independent of the method of stimulation. Different methods of stimulation have been used to test this hypothesis.\(^{(80)}\) Stimulation with 100 µM nicotine, results in the highest frequency response ($1.2 \pm 0.2$ Hz), whereas at a lower concentration (10 µM) the response is much slower ($0.5 \pm 0.2$ Hz). Both the nicotinic agonist carbamylcholine (1 mM), and KCl (60 mM) give a similar response ($0.7 \pm 0.2$ and $0.6 \pm 0.2$ Hz, respectively). The mean ± SEM (standard error of the mean) spike areas for the different stimulants is $1.19 \pm 0.9$ pC for K$^+$, $0.98 \pm 0.13$ pC for carbamylcholine, $1.04 \pm 0.16$ pC for 10 µM nicotine, and $1.19 \pm 0.10$ pC for 100 µM nicotine. Clearly, the frequency of the spikes increases with the intensity of the stimulus. However, the average quantity of catecholamine in each spike does not significantly differ with the intensity or type of stimulant used. While previous experiments in other laboratories have provided evidence for the quantized nature of neurotransmitter release, results from these studies were the first to provide direct chemical evidence for exocytosis. Further support for these conclusions was provided by Chow et al.\(^{(82)}\) In this study, it was found that the time-averaged signal of the carbon-fiber microelectrode closely resembled the derivative of the membrane capacitance trace (Figure 13). Membrane capacitance is proportional to the cell surface area and increases when individual vesicles fuse with the plasma membrane during exocytosis.\(^{(83)}\)

Since the initial studies, bovine adrenal cells have been one of the most widely used cell types in single-cell amperometry experiments. From these experiments, an incredibly large amount of information has been generated which has helped further our basic understanding of exocytosis, the fundamental means by which chemical communication takes place between cells in the nervous system, at the single-cell level. Several studies have investigated how conditions of the extracellular environment, such as temperature,\(^{(84)}\) osmolarity,\(^{(85)}\) and pH,\(^{(86)}\) affect the release of catecholamines from single chromaffin vesicles. Amperometry has also been used to dissect different temporal stages of vesicular catecholamine release at bovine adrenal cells,\(^{(87–90)}\) Chow et al.\(^{(82)}\) for example, reported a delay in vesicle fusion compared to neuronal systems and a small peak or “foot” at the onset of vesicular release events. Schroeder et al.\(^{(91)}\) also proposed that there are three distinct stages of exocytosis at bovine adrenal cells that include formation of a fusion pore, pore expansion to release catecholamine, and a final dissociation of the intravesicular matrix. Bovine adrenal cells have been used with amperometry and in conjunction with other single-cell techniques to learn more about the role of Ca$^{2+}$ and Ca$^{2+}$ channels in the exocytotic process.\(^{(92–97)}\) By using small (1 µm) flame-etched carbon-fiber electrodes, it has been possible to map the surface of adrenal cells and identify the existence of spatially localized release sites.\(^{(98)}\) Amperometry at single bovine adrenal cells has also been used to study the regulatory role of autoreceptors in exocytosis.\(^{(99)}\) More detailed discussions of findings from these studies and those discussed in the following sections may be found in the literature.\(^{(100–104)}\)

### 6.2.2 Rat Pheochromocytoma (PC12) Cells

PC12 cells are an immortalized cell line derived from rat adrenal chromaffin cells.\(^{(105)}\) These cells have been widely used as a model for adrenal chromaffin cells and

![Figure 13](Image 339x572 to 547x734)
sympathetic neurons. PC12 cells are an attractive model neuronal system owing to their ability to differentiate into neuronal-type cells upon treatment with nerve growth factor (NGF). Additionally, like sympathetic neurons, PC12 cells can synthesize acetylcholine, as well as the catecholamines dopamine and norepinephrine.\(^{106,107}\)

Using amperometric detection at carbon-fiber electrodes, catecholamine release has been observed at the zmol level from single PC12 cells in culture.\(^{108}\) The amperometric response at a single PC12 cell following three successive stimulations with both 1 mM nicotine and 105 mM K\(^+\) is compared to that of a control in Figure 14. The shape of each transient is similar to those observed from bovine adrenal cells\(^{80}\) except that the average charge for each transient is significantly smaller. Individual current spikes have an average half-width of 9.3 ± 0.1 ms and the average catecholamine content calculated using the area under each current transient and Faraday’s law is 190 ± 3.5 zmol.\(^{108}\)

Following treatment with NGF, PC12 cells extend processes.\(^{109}\) Along these processes, are bulbous regions (1–2 µm diam.), referred to as varicosities. Zerby and Ewing\(^{110}\) have used PC12 cells treated with NGF to investigate how the site of exocytosis changes during the differentiation process. To investigate these changes, beveled carbon-fiber microelectrodes have been placed at several different locations on differentiated PC12 cells. Experiments carried out between days 10 and 14 of culture show no release from the cell body (\(n = 3\)), only occasional responses from the smooth regions of the neurites (\(n = 5\)), and frequent release when the electrode is placed at a varicosity (\(n = 16\)). Additionally, the average vesicular catecholamine content observed at varicosities is not significantly different from that observed at the cell body of undifferentiated cells. These results lend some insight into functional changes that occur during differentiation and indicate that during differentiation the relocation of release sites to PC12 varicosities does not significantly alter the mean catecholamine content of individual vesicles.

The time resolution of carbon-fiber microelectrodes not only allows the detection of single exocytotic events, but also provides an excellent means by which to monitor the time course of the stimulus–secretion process. PC12 cells possess both nicotinic and muscarinic receptors that trigger exocytosis through two different mechanisms. Nicotine causes a change in the conformation of the nicotine receptor opening channels permeable to Na\(^+\). The influx of Na\(^+\) causes depolarization of the cell membrane which opens voltage-sensitive Ca\(^{2+}\) channels that allow Ca\(^{2+}\) into the cell to cause exocytosis.\(^{111}\) Muscarine activates exocytosis through muscarinic receptors that act through intracellular second messengers to release Ca\(^{2+}\) from intracellular stores.\(^{112}\) In contrast to nicotine and muscarine, K\(^+\) causes exocytosis through direct membrane depolarization. Zerby and Ewing have used amperometry at single PC12 cells to investigate how these different mechanisms affect the time course or latency of the
Their results have shown that while the average vesicle catecholamine content is unaltered by the different mechanisms of release, their latencies (time between application of the stimulant and onset of exocytotic events) vary significantly. The mean latencies for each type of stimulation are reported as: 6 ± 1 s for K\(^+\) (105 mM), 37 ± 5 s for nicotine (1 mM), and 103 ± 11 s for muscarine (1 mM). Figure 15 shows representative amperograms obtained using the three different stimulants. Interestingly, these results are in agreement with similar measurements made at single rat adrenal cells.\(^{114}\)

Several studies have used PC12 cells to investigate how different pharmacological agents effect the average catecholamine content of PC12 vesicles. For example, PC12 vesicular dopamine levels have been shown to decrease when cells are exposed to amphetamine and reserpine.\(^{69,115}\) Recently, Pothos et al. have used amperometry at single PC12 cells to investigate the effects of D\(_2\) autoreceptors on the exocytotic release of neurotransmitters. By treating PC12 cells with the D\(_2\) agonist quinpirole, it was possible to decrease the quantal size of release events by approximately 50\%.\(^{116}\) In contrast to results obtained with reserpine and amphetamine, these results provide evidence for receptor-mediated mechanisms that can decrease quantal release. The size of release events detected at PC12 cells has also been modulated by exposing cells to the catecholamine precursor L-3,4-dihydroxyphenylanlanine (L-Dopa). Following exposure to 50 \(\mu\)M L-Dopa for 40 to 90 min, the average size of quantal events is increased to 251\% of control values.\(^{117}\)

### 6.2.3 Mast Cells, Pancreatic \(\beta\)-cells, and Rat Melanotrophs

Beige mouse mast cells have been utilized for amperometric investigations of the secretory agents histamine and serotonin. Histamine and serotonin are easily oxidized molecules and are important in the nervous and immune systems of mammals. One advantage of using this cell system is the large size of the vesicles present. The larger vesicles allow release to be more easily correlated with simultaneous changes in membrane capacitance.\(^{118}\) Using amperometric methods, histamine and serotonin have been shown to be co-released from single mast cell vesicles.\(^{119}\)

Amperometric techniques have also been extended to pancreatic \(\beta\)-cells and rat melanotrophs, secretory cells not normally considered as model systems for studying neurotransmission. Pancreatic \(\beta\)-cells secrete insulin in response to glucose levels in the body. The common link between insulin secretion from \(\beta\)-cells and the other secretory cells described is that insulin is stored in vesicles and secreted via exocytosis. Membrane-potential experiments with intracellular microelectrodes\(^{120}\) and amperometric monitoring\(^{121}\) of insulin secretion, using chemically modified electrodes, have been carried out at individual pancreatic \(\beta\)-cells in an effort to better understand how these cells regulate blood sugar levels in the body. Kennedy et al. have further investigated secretion from \(\beta\)-cells using chromatographic methods and have confirmed that the secreted products are indeed insulin.\(^{122}\)

Peptide hormones are necessary for many biological functions and understanding how they are stored and secreted at the single-cell level is extremely important. Kennedy et al. have demonstrated that it is possible to detect the exocytotic release of peptides at single rat melanotrophs. The secretion of peptide hormones can be detected electrochemically by the oxidation of tryptophan and tyrosine residues found in the proopioiortin cleavage
products. The calcium-mediated release of β-melanocyte stimulating hormone has also been measured at a carbon-fiber electrode placed on a single rat melanotroph.\textsuperscript{125}

6.2.4 Invertebrate and Mammalian Neurons

Exocytotic events at single neurons from the pond snail \textit{Planorbis corneus}\textsuperscript{124,125} and the leech \textit{Hirudo medicinalis}\textsuperscript{126} have been studied using extracellular voltammetry. Bruns and Jahn\textsuperscript{126} have described electrochemical detection of serotonin release from isolated Retzius cells of the leech \textit{Hirudo medicinalis}. Single leech Retzius neurons have been cultured and a carbon-fiber electrode placed at the axonal stump and the cell body. Two types of exocytotic responses have been observed, one interpreted as resulting from serotonin release from small clear synaptic vesicles and the other from large dense-core vesicles. Release from the small clear vesicles appears to occur more rapidly (faster time constant) than from the large dense-core vesicles, which are more randomly distributed throughout the cell. It has been suggested that the faster rate observed for the small clear vesicles is due to the discharge of their contents on a submillisecond timescale through an undilated fusion pore.

Using single-cell amperometry, Chen et al.\textsuperscript{124} have found that stimulation of the giant dopamine neuron of the pond snail \textit{Planorbis corneus}, with elevated KCl, results in massive exocytotic release from the cell body (Figure 16). Since norepinephrine and epinephrine have not been detected in the giant dopamine cell,\textsuperscript{127} it appears that the observed current transients are due to the release of dopamine from the cell body. Capillary electrophoresis with electrochemical detection has been used to verify that dopamine, indeed, is being released. The current transients observed from the cell body have rise times between 2 and 5 ms, an average base width of 14 ± 0.8 ms (\(n = 13\) cells, 12,324 transients), and are not observed in the absence of Ca\(^{2+}\).

In addition to the large number of vesicular release events at the cell body, the amount of dopamine released from the vesicles has an interesting distribution.\textsuperscript{124,125} When the area of each spike is converted into vesicular content and plotted as a histogram, a bimodal distribution is observed in which each phase drops off exponentially (Figure 17a). To correlate the content of release events with vesicle radii, it has been assumed that the catecholamine concentration within each vesicle is constant.\textsuperscript{128} In contrast to results obtained from other cell types,\textsuperscript{128} when release events from the giant dopamine cell are plotted against the cube root of vesicle content two distinct Gaussians can clearly be seen in the histogram. These results suggest that there are at least two distinct classes of vesicles or release events occurring at this cell (Figure 17b). Results from the \textit{Planorbis} system have also shown that amphetamine differentially alters the catecholamine content of the two classes of vesicles\textsuperscript{125} and that release events at the cell body occur in a bursting pattern with regular time intervals between individual events (Figure 16).\textsuperscript{129}

While much has been learned by studying exocytosis at model neuronal systems and invertebrate neurons, efforts have also been focused on directly analyzing exocytosis at single mammalian neurons from the central nervous system (CNS) and peripheral nervous system (PNS). Developing superior cervical ganglion neurons from

Figure 17 Histograms of the frequency of release events vs the amount of neurotransmitter released from the dopamine cell of Planorbus. (a) Frequency vs attomoles of dopamine released (16 cells, 18,456 events). Only release events with base widths less than 40 ms were considered. Wider transients, which made up less than 2% of the total number and mostly appeared to contain contributions from more than one vesicle (appearing as doublets and shoulders), were excluded in the calculations. Based on the results obtained from 16 cells, the average vesicle content was 1.36 ± 0.53 amol (means ± s.d.), equivalent to 818,000 ± 319,000 molecules of dopamine. (b) Frequency vs the cubed root of attomoles of dopamine released (16 cells and 18,456 events). (Reproduced from J. Neuroscience, 15(11). © 1995 with permission.)

neonatal rats, for example, have been investigated with amperometric methods and vesicular release has been detected at varicosities along axons from these neurons following the application of potassium or black widow spider venom. Zhou and Misler report a median spike charge of 11.3 femtocoulombs, which corresponds to 35,000 catecholamine molecules per release event (58 zmol). These values are similar to those obtained for release events associated with small clear vesicles from leech Retzius neurons.

Recently, two studies have used amperometry to investigate the quantal release of neurotransmitters from CNS neurons. Pothos et al. adapted amperometric methods to directly observe quantal dopamine release from axonal varicosities of midbrain dopamine neurons. Events were elicited by high K⁺ or α-latrotoxin, required extracellular Ca²⁺, and were abolished by reserpine. The characteristics of these events indicated that, on average, 3000 molecules were detected over 200 µs, parameters much smaller and faster than those associated with release events detected at other vertebrate preparations.

The number of dopamine molecules detected per event increased to 380% of control values after cells were exposed to glial-derived neurotrophic factor and to 350% of control values after exposure to L-Dopa. These results indicate that quantal size is not invariant in CNS neurons.

Substantia nigra neurons release dopamine from their somatodendritic regions. However, previous studies had not been able to determine whether dopamine release occurred via exocytosis or some nonvesicular mechanism(s). To shed light on this process, Jaffe et al. have used amperometry at carbon-fiber microelectrodes to assay catecholamine secretion from the cell bodies of substantia nigra neurons in rat midbrain slices. Detected secretion events had charge integrals ranging from a few to several hundred femtocoulombs. While local application of glutamate enhanced the frequency of events, the mean area of the spikes was not changed. The addition of Cd²⁺, a blocker of voltage-dependent Ca²⁺ channels, to the cells blocked the stimulatory effects of glutamate. Together, these results suggest that dopamine...
is released from the cell body region of substantia nigra neurons via exocytosis.

7 CONCLUDING REMARKS AND FUTURE DIRECTIONS

Understanding communication between mammalian neurons is the ultimate goal of most neuronal studies. Since the initial experiments in Adams’ laboratory some 30 years ago, several developments have helped to push voltammetry to the forefront of available technologies. Today, voltammetry is being used in many different ways by chemists and neuroscientists to study fundamental processes related to neuronal communication. Fast scan rate cyclic voltammetry at microelectrodes combined with electrical stimulation has proven to be a very powerful means for detecting neurotransmitter dynamics in vivo and in vitro. These methods have been used to identify released neurochemicals, monitor how drugs affect neuronal communication, investigate the kinetics of neurotransmitter release and uptake, and further our understanding of the basic process of neurotransmission in the brain.

With the development of microelectrodes, many of the advantages of voltammetry have been exploited and used to study neurochemical processes both inside and at the surface of single cells and neurons. The small size of microelectrodes makes it easy to investigate spatially discrete regions of release on a single cell with the sensitivity and response time necessary to detect the rapid exocytotic release of minute amounts of neurotransmitters. The large amount of information that has been generated using single-cell electrochemical methods attests to the utility of this technology. In its current state, voltammetric methods are best suited to study the neurochemistry of biological systems that utilize easily oxidized neurotransmitters. Combined with enzyme-based electrodes and other chemically modified electrodes, a new group of electrochemical sensors promises to move this technology into the area of monitoring molecules that are normally not easily oxidized in biological microenvironments (key developments in this area have been published). It seems likely that some of the important molecules to be examined in the future will be glutamate, acetylcholine, peptides, and NO.

Future developments will probably also include the development of nanometer-size electrochemical probes to access the small synaptic gap. Looking back on the developments that have already taken place, it seems logical that intra-synaptic measurements will be the next frontier in which microelectrodes will be used for the electrochemical detection of neurotransmitters.

ELECTROANALYTICAL METHODS

The determination of electrochemical mechanisms by electrochemical techniques is very efficient in organic electrochemistry. In contrast to the electrochemistry of small molecules and ions, the electron transfers on organic compounds are mainly outer-sphere electron transfers following a Marcus–Hush law. Hence these fast electron transfers open up the possibility of obtaining kinetic limitation by the associated homogeneous chemical reactions.

The classical methods for these determinations are stationary techniques such as rotating disk electrode voltammetry (RDEV) and polarography but also more powerful methods, involving large-amplitude transient methods: linear sweep voltammetry (LSV), cyclic voltammetry (CV) and double-step chronoamperometry (DSC) allow the time window to be extended to thousands of microseconds; 1 µs can be reached with the use of ultramicroelectrodes. When the chemical reaction is the rate-determining step, the response, i.e. current as a function of time (or potential), provides information about the nature of this reaction and in many case allows the measurement of its rate constant. Characteristic behaviors are detailed for the principal chemical reactions preceding (C + E) or following (E + C) the electron transfer.

Organic electrochemical mechanisms often involve several electron transfers. The influence of homogeneous electron transfers is underlined in particular for two-electron reductions or oxidations and also in redox catalysis. The possibility of an electron transfer concerted with a chemical reaction is characterized. Some examples of mechanisms and kinetic determinations are given in the field of widely used organic electrosynthetic processes.

1 INTRODUCTION

An organic electrochemical process involves electron transfers on an organic molecule. Such processes are possible with a great number of organic compounds and are usually conducted in an electrolytic cell where electron transfers are located at the interface between an electrode and a conducting solution containing the compound to be reduced (electron addition) or to be oxidized (electron removal).

In the field of organic chemistry, a simple electron transfer never occurs alone, with the exception of the electrochemical preparation of stable free radicals. An organic electrochemical mechanism is an association of electron transfers and chemical reactions. Hence an electrochemical reaction appears as a sequence of three kinds of simple phenomena:

- electron transfer on organic species at an electrode surface; these species are usually in the solution but
2 ELECTROANALYTICAL METHODS

2 ELECTROCHEMICAL TECHNIQUES USED FOR THE DETERMINATION OF ORGANIC ELECTROCHEMICAL MECHANISMS

2.1 Cells and Electrodes

As organic compounds are usually insoluble in water, most electrochemical studies of potential or current are fixed on an electrode. The nature of this electrode, the solvent used and the other reactants in the medium are important parameters in allowing a particular global electrochemical reaction to occur from the reactant to one or several products. Some books deal with the more interesting processes in this field.\(^1\)

The purpose here is mainly to describe how it is possible to determine this sequence (or some part of this sequence) from electrochemical measurements by analyzing the electrical response when using electrochemical techniques at the level of small electrodes (microelectrodes) set in the initial solution. As described in several textbooks,\(^4,5\) the kinetics of the overall process are the result of the kinetics of the above three kinds of phenomena, but in many cases the global kinetics are a function of only a few key steps. The analysis of the electrical response on the microelectrode, associated with the description of the final products, is an efficient tool in the determination of this mechanism.

The most common reference electrode is a saturated calomel electrode (SCE) in water. In fact, it is very often used in all media provided that a salt-conducting separator is introduced between the two solutions. In an aprotic medium, other reference electrodes are used, e.g. silver–silver ions in acetonitrile or silver–silver chloride.\(^10\) The normal hydrogen electrode is never used in practical experiments.

According to readings from the potentiostat and from the electrochemical method used, it is possible to indicate suitable dimensions of the working electrode. For classical methods, millimeter-sized electrodes are used, but for very fast transient methods the dimensions can reach 1 \(\mu\)m. In order to interpret the electrochemical response,
an analysis of the electrical circuit of an electrochemical cell with its connection to the potentiostat must be given (Figure 1).\(^{(4,5,11)}\) The effect of the double-layer capacitance will be discussed later. Recent potentiostats permit the minimization (without being able to suppress completely the ohmic drop for stability reasons) of the value of the uncompensated resistance \(R_u\) by a positive feedback compensation.\(^{(12)}\) A current measurer is also associated with the electronic device. The readings of these electronic devices are a function of the technique used. If rapidly varying working potentials are involved, the potentiostat response has to be short and requires the use of large bandpass amplifiers.

It must be noted that although in the preparative scale up some separation between the working compartment and the auxiliary compartment often occurs, this separation is not necessarily at the level of the mechanism determination since the concentration perturbation stays in the vicinity of the working electrode and therefore the reactions at the auxiliary electrode do not affect the process. Consequently, the analysis that is developed here is not directly applicable to coupled reduction and oxidation reactions where products produced on one electrode interfere with the electrochemical reactions on the other electrode.

In order to describe the different techniques that are used, we shall first describe, briefly, the electrical response for a single, fast, one-electron transfer neglecting secondary phenomena and more specifically ohmic drop and double-layer capacitance. Fast electron transfer\(^{(5,13)}\) means that the kinetics of the electron transfer do not interfere with other limiting kinetics and that we can apply the Nernst law to this simple electron transfer (Equations 1 and 2):

\[
A + e \leftrightarrow B
\]

\[
E = E^0 + \frac{RT}{F} \ln \left( \frac{C_A^0}{C_B^0} \right)
\]

where \(C_A^0\) and \(C_B^0\) are the concentrations of A and B at the electrode, \(E\) is the electrode potential and \(E^0\) is the standard potential of the couple A/B. The initial concentration of only electroactive species A present in solution is \(C^0\), with an order of magnitude for this concentration of \(10^{-3}\) M. The example here is of a reductive process but transposition to oxidation is easy.

Because we are assuming that no chemical complications are involved, only transport phenomena are kinetically determinant. In fact, the transport phenomenon is mainly diffusion and under certain conditions convection for the reactants and the products. This is because in the solution as a large excess of supporting electrolyte is present (the concentration \(C^0\) remains very low compared with the concentration of electrolyte), so the migration of the charged species involved in the electrode reaction is restricted to a very narrow double-layer region (a few ångströms) and, as seen below, very narrow compared with the diffusion layer.\(^{(5,14)}\) Hence we can neglect this migration effect for all the described techniques and the diffusion phenomenon can be explained by a simple relationship according to Fick’s law.

### 2.2 Stationary Techniques

RDEV\(^{(5,14,15)}\) is a method where the working electrode is a small conducting disk with a surface ranging from 1 to 10 mm\(^2\). Thus a large amount of material can be used. Laminar flow is involved for moderate rotation speeds and the concentration profiles for the reactants and the product are calculated, taking into account the forced convection produced by the rotation of the electrode. The current at the electrode is dependent on potential but reaches a stationary value for any imposed potential (Figure 2a and b).

The Nernst approximation applies and we can replace the actual profile by a linear gradient in a diffusion layer (Equation 3):

\[
\delta = 4.98 D^{1/3} v^{1/6} w^{-1/2}
\]
where $D$ is the diffusion coefficient ($\text{cm}^2$), $v$ the kinematic viscosity ($\text{cm}^2 \text{s}^{-1}$), $\omega$ the angular rotation rate (rpm) and $\delta$ is expressed in centimeters. In this diffusion layer, a stationary profile is obtained and a linear variation of the two concentrations is observed. The possible rotation rate is between 50 and 20,000 rpm and the corresponding thickness of the diffusion layer is between $4 \times 10^{-3}$ and $4 \times 10^{-4} \text{cm}$.

Polarography is the oldest of all electrochemical techniques. A dropping mercury electrode serves as the working electrode, imposing severe limitations on reactions on this metal. The current law seems rather complex because this method involves a moving sphere, the surface area increasing until the drop falls. The current varies with time yet at the level of the maximum (or the average) current, a satisfactory approximation is a stationary regime in which the Nernst approximation (linear profiles) is applied, with a diffusion layer thickness in relation to the drop time $\theta$ (Equation 4):

$$\delta = \left(\frac{3\pi D\theta}{\eta}\right)^{1/2}$$

(4)

As the drop time is variable only within a narrow window ($1–10$ s), the thickness of the diffusion layer is only between $4 \times 10^{-3}$ and $10^{-2} \text{cm}$, leading to a very small variation in the experimental parameters.

With both stationary techniques, it is possible to scan the potential very slowly and thus obtain a current–potential curve (voltammetric curve). This gives a clear picture of the range of potential that must be applied in order to conduct the electrochemical reaction. The characteristic values of this plateau-shaped curve are the half-wave potential $E_{1/2} = E^0$ and plateau current $i = FSDC^0/\beta$.

As a complement to the RDEV and with the purpose of detecting the product obtained on the disk in the electrochemical reaction and to see if this intermediate is decomposed by a chemical reaction, rotating ring-disk electrode voltammetry (RRDEV) is used. The working electrode is now a disk as in RDEV, surrounded by a concentric ring separated from the disk by an insulator. The gap between disk and ring must be small to ensure that species produced on the disk can easily reach the ring. The potentials of the disk and the ring are controlled independently. In the case of a simple electron exchange, if the potential of the ring is set at a value more positive than the reduction potential of A and if the potential of the disk is slowly changed from positive to negative as in an RDEV experiment, a wave of similar shape (with a plateau for a negative potential of the disk) is also obtained on the disk during this experiment. The current obtained on the ring is the current of reoxidation of B and the height of this wave depends on the geometric dimensions of the electrode but will always be smaller than the reduction current.

2.3 Transient Techniques

Two kinds of transient techniques are described. At the level of mechanism investigations, large-amplitude techniques are usually more adapted to the problem, since they have the same advantage as stationary techniques of easily visualizing the electrochemical process. These techniques also allow a large range for the time window. LSV and CV are powerful tools in this area.

The working electrode is a stationary disk or sphere with an area in the range of $1 \text{mm}^2$ and the working electrode potential is imposed as a linear function of time (LSV). Very often, the potential returns linearly to the initial value (CV). The sweep rate $v$ is the most important
parameter because it controls the rate of diffusion of the species at the electrode and thus plays a role analogous to the rotation speed in RDEV. This sweep rate can be varied between 0.1 and a few thousand V s\(^{-1}\).

In the case of a simple electron transfer, when the potential is swept within the potential range where the electrochemical reaction is, at the beginning (initial potential), nonoperative and completely occurring (inversion potential), the curve shown in Figure 3 is obtained.

A convenient experimental characterization of the current–potential curve is measured according to the height, the location and the width of the peak for the first and second parts of the sweep.\(^{11,17,18}\)

For the first scan, these cathodic peak characteristics for a single fast transfer are expressed by Equations (5–7):

\[
i_p = 0.446FSC^0D^{1/2}\left(\frac{Fv}{RT}\right)^{1/2}
\]  

Peak current: \(i_p\)

\[
E_p = E^0 - 1.11\left(\frac{RT}{F}\right)
\]  

Peak potential: \(E_p\)

\[
E_{p/2} - E_p = 2.20\left(\frac{RT}{F}\right)
\]  

Peak width: \(E_{p/2} - E_p\)

where \(E_{p/2}\) is the potential corresponding to a current intensity equal to half that peak current.

For the reverse part of the potential sweep, if the curve is calculated from the prolongation of the diffusion part of the first part, the same peak current (anodic current) and peak width are found with an anodic peak potential (Equation 8) of

\[
(E_p)_2 = E^0 + 1.11\left(\frac{RT}{F}\right)
\]  

leading to a cathodic and anodic peak separation (Equation 9) of

\[
\Delta E_p = 2.22\left(\frac{RT}{F}\right)
\]  

Other useful large-amplitude techniques in the field of organic electrochemical mechanism determination are potential step chronoamperometry (PSC) and DSC.\(^{5,11,17}\) In PSC, the stationary electrode is stepped from a rest potential (no reduction of A) to a more negative value, markedly more negative than the standard potential \(E^0\) so that the concentration of A at the electrode is zero. The cathodic current is only controlled by diffusion and can be expressed by Equation (10):

\[
i = \frac{FSC^0D^{1/2}}{\left(\pi t\right)^{1/2}}
\]  

Moreover, in DSC, after a time \(\theta\), the potential is stepped back to the initial potential and, as for a CV experiment, the reoxidation curve is exactly the same as the cathodic curve if the current is measured starting from the prolongation of the cathodic curve (Figure 4).

An easy way to analyze the reoxidation curve is to measure the anodic current from the current axis at a time \(2\theta\) (double the inversion time). The ratio between the anodic and the cathodic currents for \(\theta\) is 0.293.

Small-amplitude transient techniques are often used for the analytical aspects of these techniques.\(^{19}\) For the purpose of determining the characteristics of the electron transfers, some aspects of square- or sinusoidal-superimposed potential [alternating current (ac) technique, also called the impedance technique]\(^{20}\)
have been developed with a range of frequency of 10−10000 Hz. It has been claimed that the second-harmonic ac technique is very efficient. These techniques consist of applying on the electrode a small-amplitude sinusoidal potential (frequency $\nu$) and a slow variation of a dc potential and detecting the amplitude and the phase of the first- ($\nu$) or second-harmonic ($2\nu$) current amplitude as a function of the dc potential. The two components in-phase and out-of-phase with the input potential are then separated. It must be noted that the second-harmonic ac technique contains the same limitation as the simple ac technique. At the level of mechanism determinations for complex sequences, these techniques are very rarely used.

2.4 Comparison of the Time Windows

For stationary techniques, the time window is determined from the mean transport (diffusion) time from the solution to the electrode and thus is $D/\delta^2$. The limitations are dependent on the hydrodynamic limitation with respect to the rotation rate in RDEV, as mentioned earlier, and dependent on the drop time in polarography.

For transient techniques, the limitations that occur are essentially due to secondary phenomena. In the preceding sections, we have assumed that the current at the electrode surface results only from diffusion in solution when an electron transfer occurs between an electrode and the organic substrate (faradaic current). However, several side effects can disturb this assumption.

To start with, a double layer is always present at the electrode interface, which leads to an additional capacitor $D_{SC}$ at the electrode surface results only from diffusion in solution when an electron transfer occurs between an electrode and the organic substrate (faradaic current). However, several side effects can disturb this assumption.

For example, in LSV, a constant capacitive current $i_c = SC_d\nu$ is obtained and it should be noted that this current is a function of the sweep rate $\nu$ as compared with the faradaic current (that is a function the square root of $\nu$). Hence, for large values for $\nu$, the capacitive component increases as compared with the faradaic current. For a concentration of substrate of about $10^{-3}$ M, these two components have the same order of magnitude for a sweep rate of a few thousand volts per second.

As previously remarked, an uncompensated resistance between the working and reference electrodes remains in a three-electrode potentiostat; even when this potentiostat is equipped with feedback compensation, part of this resistance remains. The total capacitive current is expressed by Equation (11):

$$i_c = SC_d\nu \left(1 - \exp \left(\frac{-t}{R_uSC_d}\right)\right)$$  \hspace{1cm} (11)
drop can theoretically be neglected because the step value in potential is chosen far enough away from the standard potential value, the effect is still present on the shape of the curve, mainly for short observation times. Moreover, the capacitive and the faradaic currents in this short-time experiment are high enough that the limitation for short times cannot be estimated merely in terms of \( R_uS_Cd \) but by about 10 or 20 times these values before which the diffusion current is not affected by the capacitive current. These high currents also prevent the use of very efficient ohmic drop compensation. Thus, the short-time limitation for this technique is 1 ms without ohmic drop compensation and 0.1 ms otherwise.

Another limitation is the effect of nonlinear diffusion on the small disk or on the sphere acting as the working electrode. This effect appears for long-time values or for low sweep rates and it can be neglected on millimeter-sized electrodes down to 0.1 V s\(^{-1}\) (or up to 1 s in PSC). Thus the sweep rate window in LSV ranges from 0.1 to 1000 V s\(^{-1}\). The time window corresponding to this sweep rate is \( RT/Fv \), a value that is of the same order of magnitude as the time occurring between the standard potential and peak potential. Hence the time window for an LSV experiment on a millimeter-sized electrode ranges from 25 \( \mu \)s to 0.25 s.

Recently, a means of obtaining higher sweep rates was found using ultramicroelectrodes\(^{23–25} \) provided that large-bandpass amplifiers were used. Disk electrodes between 1 and 10 \( \mu \)m are now commercially available for this purpose. As shown previously, three parameters must be minimized in order to shorten response times (or increase sweep rates): \( R_uS_Cd, R_u, \) and \( i_c \) as compared with \( i_F \). A possibility is to decrease the size of the electrode. In this way not only \( R_uS_Cd \) is decreased but also the resistance near the working electrode (the important part of the resistance between the working and reference electrodes) is more or less a function of the inverse of the radius of this electrode. Thus \( R_u \) is decreased by a factor of 100 between a millimeter-sized and a 10- \( \mu \)m electrode. Figure 6 illustrates the possibility of the use of these ultramicroelectrodes, shown with a sweep rate up to 10\(^6\) V s\(^{-1}\).

The use of an ultramicroelectrode is not restricted to LSV; we can also use it in DSC. The gain obtained

compared with a millimeter-sized electrode is about two orders of magnitude, which leads to short time values of about 1 µs.

With an ultramicroelectrode, a limitation due to spherical diffusion occurs at a higher sweep rate (about 100 V s$^{-1}$) but does not present a real problem because at lower sweep rates a stationary response is obtained even if a stationary electrode is used. From this change in the diffusion regime, an elegant method for determining the exchange number of electrons in a complex mechanism is developed.\(^{(25)}\)

Table 1 summarizes the various possibilities of the more commonly used methods in the analysis of organic electrochemical mechanisms.

In addition to the classical electrochemical methods, an effective method using photoinjection of electrons by means of a laser flash has been described,\(^{(26)}\) as shown in Figure 7.

The advantage of this method is that it produces solvated electrons that react with a reducible neutral compound very close to the surface. Therefore, analysis of the chemical reaction in this region near the electrode is possible. The potential of the electrode can be fixed in a potential region beneath the reduction potential of the initial compound. The measurement is the residual photoinduced charge transferred from the electrode to the solution. If the intermediate product (anion radical) is stable, the response is similar to the response of the recombinination of the free electrons produced in the solution without any reducible compound (the solvated electron and the radical anion are reoxidized at the electrode). However, if the intermediate compound cleaves very quickly, yielding an unoxidizable compound, the residual photoinduced charge increases. According to the analysis time for the residual photoinduced charge at the end of the laser flash, a first-order kinetic constant can be obtained between $2 \times 10^{-3}$ and $10^{-8} – 10^{-9}$ s$^{-1}$, leading to the shortest time window of only a few nanoseconds.

However, with the preceding performance, this method is restricted to an aqueous solution and even in DMF this application is difficult. On the other hand, this method allows the study of the second electron transfer when a very fast cleavage occurs at the level of the first step.\(^{(27)}\) The reduction of radicals giving anions can be characterized via its standard potential and its kinetics of electron transfer even in an aprotic medium such as DMF. Some results are given in the following section. At the level of the determination of electrochemical properties of transient radicals, another effective method is used, photomodulation voltammetry (PMV),\(^{(28)}\) which, yields either cations in oxidation or anions in reduction. If these radicals are destroyed by a dimerization process, the measurement is always possible even when this reaction reaches the diffusion limit.

In addition to the electrochemical methods described here, the determination of electrochemical reaction mechanisms is often assisted by spectrometric methods ex situ or in situ. In the latter case, spectroelectrochemical techniques with ultraviolet/visible (UV/VIS), infrared (IR) or electron spin resonance (ESR) spectroscopy are used. These techniques are described in other articles.

![Figure 7 Principle of the photoinjection of electrons method in the case of the reduction of a substrate RX.](image)
3 CHARACTERISTICS OF ELECTRON TRANSFERS FOR ORGANIC COMPOUNDS

Two characteristics of the electron transfer are of particular importance because they open up possibilities for the use of electrochemical techniques in mechanism determinations. The first is the weak adsorption of organic reactants, products and intermediates when aprotic solvents and classical inert electrodes are used. Hence most organic mechanisms deal only with homogeneous chemical reactions and electron transfer reactions at the electrode. The second is related to the kinetics of electron transfer in organic electrochemistry.

3.1 Theory

Electron transfers constitute one or several elementary steps of the mechanism of electrochemical reactions. As organic species are molecules of significant size, the Marcus–Hush theory\(^ {29,30}\) is especially adapted to the description of the kinetic laws of this transfer. This theory was developed in the case of an electron transfer occurring without any breaking or any formation of chemical bonds, still taking into account changes in the solvation (changes in orientation of solvent molecules near the molecule) and changes in bond lengths or angles. The theory of electron transfer at the electrode is completely associated with the theory of homogeneous electron transfer when the electron exchange occurs between two molecules differing only by one oxidation degree.\(^ {30–32}\)

From a theory similar to that concerning activated complexes, the electron transfer rate can be written for an adiabatic process, and according to the Franck–Condon principle, which states that the slow step involves the heavier particle, leading to kinetics determined by the changes at the level of the reactants and the product. The kinetics can be expressed using Equations (12) and (13):

\[
k_S = Z_{ad} \exp \left( -\frac{\Delta G^*}{kT} \right) \tag{12}
\]

with

\[
\Delta G^* = \left( \frac{\lambda}{4} \right) \left( 1 + \frac{\Delta G^0}{\lambda} \right)^2 \tag{13}
\]

where \(Z_{ad}\) is the collision number for the heterogeneous reaction, \(\Delta G^*\) the free energy of activation, \(\Delta G^0\) the standard free energy of the reaction (\(\Delta G^0 = 0\) at the standard potential) and \(\lambda\) a reorganization term composed of solvational (\(\lambda_0\)) and internal (\(\lambda_i\)) components. The standard activation free energy (intrinsinc barrier) for \(\Delta G^0 = 0\) is then given by Equation (14):

\[
(\Delta G^*)^0 = \frac{\lambda_0 + \lambda_i}{4} \tag{14}
\]

In an outer-sphere electron transfer with small internal reorganization, so that the solvent reorganization term \(\lambda_0\) is the largest, this term can be estimated from the ionic radii of reactant and product and a distance \(d\) that expresses the location of the electron exchange (Equation 15):

\[
\lambda_0 = (\Delta e)^2 \left( \frac{1}{a} - \frac{1}{d} \right) \left( \frac{1}{\varepsilon_{op}} - \frac{1}{\varepsilon_S} \right) \tag{15}
\]

where \(\Delta e\) is the change in charge between reactants and product, \(\varepsilon_{op}\) and \(\varepsilon_S\) are the optical and static dielectric constant of the solvent and the estimation of \(d\) is 2\(a\) according to Marcus\(^ {29}\) and 1/\(d = 0\) according to Hush.\(^ {29}\)

From this theory and for large-sized molecules such as aromatic compounds in aprotic solvents where only solvent reorganization is involved, the rate constant of the electron transfer can be estimated. For radii in the range 2–5 Å, values of \(k_S\) between 1 and 10 cm s\(^{-1}\) were estimated. It must be noted that the rate of the electron transfer is quadratic with the potential having a value of \(\sigma(d\Delta G^*/d\Delta G^0)\) equal to 0.5 at the standard potential of the reaction.

The internal or vibrational term provides an important contribution when some bond lengths or bond angles are changed during the electron transfer. This is important, for example, in the reduction of an aliphatic radical in an anion.

It is also possible to estimate the kinetics of the electron transfer when this transfer is concerted with a bond cleavage (Equation 16):

\[
A - X + e^- \rightarrow_{\text{equiv}} A^* + X^- \tag{16}
\]

As with the Marcus–Hush theory, the Born–Oppenheimer approximation is assumed to be applicable and the reaction to be adiabatic. The potential energy surfaces for the reactants and products depend now on three kinds of reaction coordinates: (1) the solvent fluctuational configuration as in the simple outer-sphere electron transfer, (2) the vibration coordinates for bonds that are not cleaved during the reaction and (3) the stretching of one bond cleaved during the reaction. These three parts are additive and for the last one the potential energy of the reactant is supposed to depend on the bond length according to a Morse curve whereas the product potential energy curve is assumed to be the same as the repulsive part of the reactant Morse curve.\(^ {33,34}\) A comparison of the potential energies for the outer-sphere mechanism of electron transfer and dissociative electron transfer is illustrated in Figure 8(a) and (b).

As a result, the standard activation free energy is now given by Equation (17):

\[
(\Delta G^*)^0 = D_a + \frac{\lambda_0 + \lambda_i}{4} \tag{17}
\]
Figure 8 Potential energy (a) for an outer-sphere mechanism of electron transfer (Marcus–Hush theory) and (b) for a dissociative electron transfer.

where $D_e$ represents the bond dissociation energy. It can easily be shown that $(\Delta G^*)^0$ can have large values compared with the outer-sphere case and that the standard potential of the redox couple involved (Equation 16) can be very different to the standard potential from the possible simple electron transfer (Equation 18):

$$
A - X + e^- \rightleftharpoons AX^{**} \quad (18)
$$

3.2 Characterization Procedures

3.2.1 Linear Sweep Voltammetry and Convolution

The analysis of the kinetics of the electron transfer must be taken into account in comparison with the always present rate of diffusion. This depends on the method used and on the time window of this method. It should be emphasized that there is a possible difficulty in ensuring that the kinetics are dependent on the electron transfer and not on other phenomena such as chemical evolution of an intermediate product.

The effect of the kinetics of the electron transfer on the curves obtained by the different electrochemical methods is illustrated via LSV and CV. As a first approach, the electronic rate law is often described with the empirical Butler–Volmer law (Equation 19):\(^5\)

$$
i = FS_kS \exp \left( -\frac{\alpha F(E - E^0)}{RT} \right) \times \left\{ (C_A)_0 - (C_B)_0 \exp \left( \frac{F(E - E^0)}{RT} \right) \right\} \quad (19)
$$

(for a reduction) where $k_S$ is the standard rate constant and $\alpha$ the transfer coefficient. It must be noted that this approach can be related to the Marcus law and, for example, when the potential is approximately equal to the standard potential, $k_S = Z_\alpha \exp(-\Delta G^*/kT)$ and $\alpha = 0.5$.

The change in the voltammetric curve occurs according to the change in $k_S$ and to the time window of the method. The operational parameter is, in fact, $k_S/(DFv/RT)^{1/2}$. As the values of $k_S$ become smaller and smaller, the more the cathodic peak potential becomes negative and the more the cathodic and anodic peaks are separated. A cathodic curve depending only on the shape of $\alpha$ is obtained for lower values of $k_S$.\(^5\)

However, as mentioned earlier, the quadratic law is predicted by the Marcus–Hush theory and its extension. Under these conditions, some different evolutions are obtained that are characterized by the standard activation free energy. The value of the apparent transfer coefficient is then a function of the gap between peak potential and standard potential. Figure 9(a) and (b) shows a comparison between these two possible approaches. The apparent transfer coefficient decreases from 0.5 in the vicinity of the standard potential when the potential is set to a more negative value.

The shape of the curve is determined by the value of the peak width (gap between peak potential and half-peak potential) (Equation 20):

$$
E_{p/2} - E_p = 1.85 \left( \frac{RT}{\alpha F} \right) \quad (20)
$$

and for all the values of $\alpha < 0.5$ this peak width is larger than for a fast electron transfer where only the diffusion is rate-limiting step. This measurement of the peak width is a good way to determine the experimental value of $\alpha_{ap}$ but not very accurate, particularly when this value is near 0.5.

A way in which to increase this accuracy is to take the convolution of the LSV curve (Equation 21):\(^5\)

$$
I = \frac{1}{\pi^{1/2}} \int_0^\infty \frac{i(v)}{(\tau - v)^{1/2}} dv \quad (21)
$$
Figure 9 CV with a slow-rate electron transfer, (a) according a Butler–Volmer law with $k_S(\text{cm s}^{-1}) = (A) \infty, (B) 0.03 (C) 5 \times 10^{-5}$ and (D) $1 \times 10^{-8}$ and (b) according a Marcus–Hush law. For curve D, comparison of the shape of the curve corresponding to the Butler–Volmer law (dashed line).

This quantity is easily calculated and is directly proportional to the diffusing reactant concentration. Hence a plateau curve identical with what is obtained using a stationary technique is obtained regardless of the kinetic law of the electron transfer that is followed (Figure 10a).

From the shape of the curve and from the different convolution curves obtained using LSV curves at several sweep rates, the kinetics of the electron transfer are measured by determining the value of $\ln k(E)$.

(Equation 22):

$$i = F S k(E) \left\{ (C_A)_0 - (C_B)_0 \exp \frac{F(E - E^0)}{RT} \right\}$$  

An example of the determination of this quantity is given in Figure 10(b), where a curvature of this relationship with potential, resulting from a Marcus-like law of the electron transfer, can be noted. The apparent transfer coefficient $\alpha_{ap}$ is obtained from Equation (23):

$$\alpha_{ap} = - \left( \frac{RT}{F} \right) \frac{d[\ln k(E)]}{dE}$$  

The standard potential is the value of the potential when $\alpha_{ap}$ is exactly 0.5.

3.2.2 Impedance Technique

This kind of determination may also be conducted using an impedance technique, mainly in the vicinity of the
standard potential for fairly fast electron transfers (quasi-reversible system). By superimposing an alternating current on a slowly variable dc potential, the faradaic resistance $R_f$ and the faradaic capacitance $C_f$ are analyzed taking into account the double-layer capacitance and the cell resistance that are obtained from a test experiment. The apparent rate constant $k(E)$ is obtained from Equation (24):

$$\log \frac{k(E)}{D^{1/2}} = -\log \frac{(R_fC_f)^{1/2}[1 + \exp((F/RT)(E - E_{1/2})/2)]}{(2\pi)^{1/2}}$$ (24)

The results obtained by this technique for a quasi-reversible system have comparable accuracy to those obtained via convolution.\(^{36}\)

### 3.3 Some Results

Organic species producing stable radicals (mainly anion radicals in reduction and cation radicals in oxidation) are for the most part aromatic and bulky molecules. Thus, the electron transfer for these molecules can be explained using the Marcus–Hush theory where the predominant effect is solvation reorganization. The transfers that occur are fairly fast and their measurement requires very short time window techniques.

Some examples of the determination of the kinetics of simple reduction processes as measured using the standard rate constant and the standard free energies of activation where DMF is the solvent are given in Table 2.

It is possible to show that a quadratic Marcus-type law is followed for the reduction of nitrodurene and tert-nitrobutane where the electron transfer is simple but slower than for the first ones. There the change in the solvation is localized at the level of the nitro group, which leads to a significant change in the solvation reorganization term.\(^{38}\) For the reduction of aliphatic radicals a significant change in the internal reorganization term explains the large standard activation energy that results.\(^{39}\)

When chemical reactions occur (the product of electron transfer is not stable), the kinetics of the electron transfer are difficult to determine, yet, as explained below, the measurement of the kinetics for very slow electron transfer is possible whatever the following chemical or electrochemical processes. For this reason, it is easy to characterize dissociative electron transfer where the $(\Delta G^*)^0$ values are high owing to the influence of the dissociation energy. Some examples of the determination of $(\Delta G^*)^0$, of values of $\alpha_{sp}$, of transfer coefficients and of the order of magnitude of the gap between the standard potential and the effective reduction potential in a voltammetric experiment are presented for the case of reductive cleavage of organic halides\(^{40,41}\) in Table 3.

All these electron transfers involve the following electrochemical elementary reaction (Equation 25):

$$R-X + e^- \rightleftharpoons R^+ + X^-$$ (25)

with a standard potential $E^0(RX/R^+X^-)$. It is important to note that this standard potential is absolutely different from the standard potential $E^0(RX/RX^*)$ in the couple (Equation 26)

$$R-X + e^- \rightleftharpoons RX^*$$ (26)

which corresponds only to a simple electron exchange on the same molecule. For example, in the case of the reduction in DMF of 9-chloromethylanthracene,\(^{41}\) $E^0(RX/R^+X^-) = -0.15$ V versus SCE and $E^0(RX/RX^*)$ is estimated by comparison with other anthracenyl compounds to be about $-1.8$ to $-1.9$ V versus SCE.\(^{42}\) The fact that the reduction potential is $-1.36$ V in LSV at 1 V s\(^{-1}\) and that this value is less negative than for the possible simple reduction reaction is proof of the efficiency of the reduction via dissociative electron transfer.

$E_m$ is the mean value of the reduction peak in an LSV experiment at 0.1 V s\(^{-1}\).
4 SIMPLE ORGANIC ELECTROCHEMICAL MECHANISMS

4.1 Nature and Classification of Coupled Chemical Reactions

In this section, the different kinds of chemical reactions that occur in organic electrochemistry and their influence on the kinetics of the overall process will be presented. For this purpose, we have chosen some simple examples where the nature of these reactions is clearly demonstrated and not merely postulated. This is an important point because in complex mechanisms not all the steps are fully elucidated as they are out of reach of characterization techniques.\(^{(5,11)}\)

The way in which these chemical reactions may be qualitatively characterized will be explained for each particular case.

4.1.1 Preceding Chemical Reaction

The reaction scheme in Scheme 1 is followed:

\[ \text{C} \xrightarrow{\text{A}} \text{A} \pm \text{e}^- \xrightarrow{\text{B}} \]

**Scheme 1**

Compound C present in solution is not electroactive in the potential range of interest and compound A must be formed through prior conversion of C. It must be noted that compound C is sometimes reducible or oxidizable directly in another range of potential. The reduction of carbonyl compound in acidic medium illustrates this behavior (Scheme 2)\(^{(1,2)}\):

\[ \text{C} + \text{O} + \text{H}^+ \xrightarrow{\text{O}} \text{C} \xrightarrow{\text{O}} \text{H} + \text{e}^- \xrightarrow{\text{C}} \text{C} \xrightarrow{\text{O}} \text{H} \]

**Scheme 2**

Reactions that thermodynamically favor C are the only ones that are easily observable and the main manifestation of this process is the height of the wave in RDEV, the peak current in LSV or the current values in a single potential step technique. If the chemical reaction is slow compared with the diffusion, the result will be a measurement of the equilibrium concentration of A, whereas if the reaction is fast, the result will be proportional to the total concentration of A and C. So, for example, in RDEV the height of a wave does not follow \( w^{1/2} \) when the time window is of the same order of magnitude as that of the rate of reaction.

4.1.2 Consecutive Reaction

A chemical reaction occurs after the electron transfer (Scheme 3):

\[ \text{A} \pm \text{e}^- \xrightarrow{\text{B}} \text{B} \xrightarrow{} \text{C} \]

**Scheme 3**

In the case where C is thermodynamically stable compared with B, this intermediate B is not stable and cannot accumulate near the electrode. As written above, this reaction is first order (or pseudo-first order if B reacts with solvent or a species in high concentration in the solution), but a second-order reaction (dimerization) is also possible. The characterization of such a process is not possible at the level of the wave or peak current but other techniques that allow the detection of the reverse current (reoxidation of B for a reduction of A) can help to visualize this type of process. Thus, with CV or RRDEV, if the lifetime of the intermediate is small compared with the time window of the method, no reoxidation current is observed. However, if the time window of the technique can be shortened compared with the lifetime of B, then nothing changes in the pattern obtained from a simple electron transfer.

Another way to detect a fast chemical reaction involves the displacement of the potential in response to the chemical reaction. The electrochemical reaction is facilitated in the presence of a chemical reaction (more positive reduction).

At the level where it is possible to determine the order of the reaction, an accurate determination of the peak potential in LSV or of the half-wave in RDEV provides an answer to the question. The displacement as a function of the initial concentration also provides information.

Some examples of consecutive reactions are given in Schemes 4–6.

First-order, bond cleavage reaction:\(^{(43)}\)

\[ \text{C} + \text{O} + \text{H}_2\text{SC}_2\text{H}_5 + \text{e}^- \xrightarrow{} \left[ \text{C} + \text{O} + \text{H}_2\text{SC}_2\text{H}_5 \right]^- \]

\[ \left[ \text{C} + \text{O} + \text{H}_2\text{SC}_2\text{H}_5 \right]^- \rightarrow \left[ \text{C} + \text{H}_2\text{S}^- \right] + \text{C}_2\text{H}_5\text{H} \]

**Scheme 4**

Pseudo-first-order reaction, protonation of a ketone by phenol:\(^{(44)}\)

\[ \text{C} + \text{O} + \text{PhOH} \rightarrow \left[ \text{C} + \text{H} \right] + \text{PhO}^- \]

**Scheme 5**
Dimerization: \[ \text{Scheme 6} \]

4.2 Kinetic Analysis for a Single Chemical Reaction Acting as the Determining Step

As explained earlier, in organic electrochemistry the electron transfers are fairly fast and homogeneous chemical reactions occur more frequently than surface chemical reactions. When electron transfer is fast, it is possible to express, using efficient methods, how the homogeneous chemical reactions (acting only with the diffusion), influence the electrochemical response. For each method used the same kind of kinetic limits are obtained but, as LSV and CV are often used, the results are presented for these methods. \(^{14}\) The sequence of electrochemical and chemical reactions are expressed by the letters E for electrochemical and C for chemical; if necessary, the order of the reaction is indicated after the letter C. \(^{13}\)

4.2.1 First-order Preceding Chemical Reaction (C + E) (Scheme 7)

As explained above, only cases where the equilibrium is displaced towards C are of interest. For each value of this equilibrium constant, three main kinetic behaviors are singled out according to the value of the forward rate constant \(k\):

- \(k \approx 0\), curve corresponding to a simple diffusion of the A species in the thermodynamically low concentration: “pure diffusion”;
- \(k \approx \infty\), curve corresponding to the reduction of the whole concentration of species \(A + C\): “pure extraordinary diffusion”;
- intermediate value of \(k\) where a plateau-shaped curve is obtained at negative potential; this “pure kinetics” case depends on the parameter \(K\sqrt{k}\) and under these conditions the plateau current obtained is independent of the sweep rate (Equation 27):

\[
i_{\text{pl}} = FSC^{0}D^{1/2}K\sqrt{k}
\]

These limiting cases are easily visualized in a kinetic diagram (Figure 11) where kinetic control intermediate zones depending on the accuracy of the determination are present between the three pure limiting zones. The two parameters are the thermodynamic constant \(K\) and the kinetic constant \(k\).

4.2.2 Consecutive Chemical Reaction

4.2.2.1 First-order Reaction (E + Cl) (Scheme 8)

The kinetic diagram with the two parameters \(k\) and \(K\) is shown in Figure 12. Here also a “pure kinetic” zone is obtained for intermediate values of \(k\) in the region of an equilibrium displaced towards C. In this pure kinetic zone, chemical irreversibility occurs (no reverse current

\[
\text{Scheme 7}
\]

\[
\text{Scheme 8}
\]
in CV) and the characteristics of the peak current are expressed by Equations (28–30):

Peak current:

\[ i_p = 0.496FSC_0D^{1/2} \left( \frac{F_v}{RT} \right)^{1/2} \]  

(28)

Peak potential:

\[ E_p = E^0 - 0.78 \left( \frac{RT}{F} \right) + \left( \frac{RT}{2F} \right) \ln \left( \frac{RT}{F} \right) \frac{k}{v} \]  

(29)

Peak width:

\[ E_{p/2} - E_p = 1.85 \left( \frac{RT}{F} \right) \]  

(30)

Thus, the peak current in a “pure kinetic” condition is proportional to the square root of the sweep rate and the peak potential is displaced to \(-(RT/2F)\ln10\) (–30 mV at 302 K) when the sweep rate is increased by one order of magnitude. This value is for a reduction reaction as in the other following schemes. For an oxidation a change in the direction of the variations is obvious.

The displacement to –30 mV at 302 K when the sweep rate is increased by one order of magnitude without any variation with the concentration of the initial species is a characteristic of the order of the chemical reaction.

### 4.2.2.2 Second-order Reactions \((E + C2)^{(47)}\)

If the chemical reaction is a second-order reaction, the same kind of kinetic zone diagram is obtained and a pure kinetic zone is also found. In fact, several coupling processes are possible and each of them can be characterized, in the “pure kinetic” zone, by the shape of the voltammetric curve in CV, by the peak potential variations with sweep rate and concentration in LSV.

\[ A \pm e^- \longrightarrow B \]  

\[ 2B \xrightarrow{k} D \]  

**Scheme 9**

**Dimerization Between Two Reduced (or Oxidized) Species \([E + C2(Ar)]\)** (Scheme 9). The characteristics of the peak current are expressed by Equations (31–33):

Peak current:

\[ i_p = 0.527FSC_0D^{1/2} \left( \frac{F_v}{RT} \right)^{1/2} \]  

(31)

Peak potential:

\[ E_p = E^0 - 0.902 \left( \frac{RT}{F} \right) + \left( \frac{RT}{3F} \right) \times \ln \left( \frac{RT}{3F} \right) \frac{kC_0}{v} \]  

(32)

Peak width:

\[ E_{p/2} - E_p = 1.51 \left( \frac{RT}{F} \right) \]  

(33)

The displacements to –20 mV at 302 K when the sweep rate is increased by one order of magnitude and to 20 mV when the concentration of the initial species is increased by one order of magnitude characterize this dimerization process.

**Dimerization Between One Reduced (or Oxidized) Species and the Substrate \([E + C2(Ar)]\)** (Scheme 10). The characteristics of the peak current are expressed by

\[ A \pm e^- \longrightarrow B \]  

\[ A + B \xrightarrow{k} D \]  

**Scheme 10**

Equations (34–36):

Peak current:

\[ i_p = 0.430FSC_0D^{1/2} \left( \frac{F_v}{RT} \right)^{1/2} \]  

(34)

Peak potential:

\[ E_p = E^0 - 0.457 \left( \frac{RT}{F} \right) + \left( \frac{RT}{2F} \right) \times \ln \left( \frac{RT}{2F} \right) \frac{kC_0}{v} \]  

(35)

Peak width:

\[ E_{p/2} - E_p = 2.27 \left( \frac{RT}{F} \right) \]  

(36)
The displacements to $-30 \text{ mV}$ at 302 K when the sweep rate is increased by one order of magnitude and to 30 mV when the concentration of the initial species is increased by one order of magnitude characterize this dimerization process.

When only one compound is electroactive, from these four simple kinetic situations (C + E, E + C1 and the two E + C2), it is possible to analyze the complex mechanisms obtained in organic electrochemistry.

One question remains concerning the possibility of considering the kinetics of the electron transfer as a non-limiting kinetic phenomenon. For example, in chemical reactions following the electron transfer in reduction, the CV curve is displaced towards increasingly positive potentials as the chemical rate constant increases. Taking into account the law of electron transfer, it appears that the apparent electron rate constant is lower at more positive potential values than at standard potentials. Hence the faster the chemical reactions are, the more the limitation by electronic transfer becomes significant. However, in many experiments, in a range up to $10^4–10^6 \text{ s}$ for the first-order chemical reaction constant, the hypothesis of fast electron transfer still remains valid.

5 COMPLEX MECHANISMS

The mechanism for electrochemical reactions is the pathway leading from the initial reactants to the final products where at least one electron transfer occurs. In many cases the electrochemical reactions on a substrate can yield several products. On the one hand, the process is potential dependent and, according to the applied potential, the nature of the products is different. On the other hand, for a certain potential, competitive sequences of reactions are possible. In this section we limit ourselves to mechanisms where only one sequence is involved (no branching reactions) and also to cases where only one substrate is electroactive.

An electrochemical mechanism is written as a succession of electrochemical steps and chemical steps and we shall focus on two main problems: (1) how to understand the reaction sequence for complex reactions and (2) to elucidate what happens when the mechanism involves several electron transfers.

5.1 Sequence of Chemical Reactions After One Electron Transfer

Consider the formation of pinacol from the reduction of a ketone in a slightly acidic medium (the ketone cannot be protonated prior to its reduction). The first electrochemical reaction is (Equation 37):

$$\text{C} = \text{O} + e^- \rightarrow \text{C}^- \text{O}^- \quad (37)$$

and successive reactions lead to the pinacol (Equation 38):

$$2 \text{C}^- \text{O}^- + 2\text{H}^+ \rightarrow \text{C} - \text{O} - \text{H} + \text{C} - \text{O} - \text{H} \quad (38)$$

Because the dimerization of the two anions is slow, the possible sequence is as shown in Scheme 11:

$$\begin{align*}
\text{A} + e^- & \rightarrow \text{B}^- \\
\text{B}^- + \text{H}^+ & \rightarrow \frac{k_1}{k_2} \text{BH} \quad \text{(Pseudo-first-order reaction)} \\
2 \text{BH} & \rightarrow \frac{k_3}{k_4} \text{D}
\end{align*}$$

**Scheme 11**

and several kinetic limiting behaviors are possible according to what the slow chemical step (rate-determining step) is, as in chemical kinetics. If reaction (i) is slow compared with reaction (ii), the kinetics and the characteristics of the electrochemical curves are those of the mechanism E + C1. For example, in LSV, the characteristics are expressed by Equations (39–41):

**Peak current:**

$$i_p = 0.496FSC^0D^{1/2} \left( \frac{Fv}{RT} \right)^{1/2} \quad (39)$$

**Peak potential:**

$$E_p = E^0 - 0.78 \left( \frac{RT}{F} \right) + \left( \frac{RT}{2F} \right) \times \ln \left( \frac{RT}{F} \right) \frac{k}{v} \quad (40)$$

**Peak width:**

$$E_{p/2} - E_p = 1.85 \left( \frac{RT}{F} \right) \quad (41)$$

Hence the peak current is, as in pure diffusion conditions, proportional to the square root of the sweep rate and the peak potential is displaced to $-(RT/2F) \ln 10 (\sim 30 \text{ mV})$ at 302 K when the sweep rate is increased by one order of magnitude.

If reaction (i) is fast compared with reaction (ii) ($k_2 > k_1$), the reaction acting as a pre-equilibrium for reaction (ii), the kinetics and the characteristics of the electrochemical curves are those of the mechanism E + C2$\text{C}_{(Art)}$ resulting in the pre-equilibrium that replaces $k_2$ by $(k_2k_1/k_3)[\text{H}^+]$, which introduces a variation with pH and more generally with concentration of other species.
occurring before the slow step. In LSV, the characteristics are expressed by Equations (42–44):

\[
\text{Peak current: } i_p = 0.430 FSC^0 D^{1/2} \left( \frac{Fv}{RT} \right)^{1/2} \tag{42}
\]

\[
\text{Peak potential: } E_p = E^0 - 0.457 \left( \frac{RT}{F} \right) + \left( \frac{RT}{2F} \right) \ln \left( \frac{RT}{F} \left( \frac{k_1k_2}{k_2} \right) [H^+] \left( \frac{C^0}{v} \right) \right) \tag{43}
\]

\[
\text{Peak width: } E_{p/2} - E_p = 2.27 \left( \frac{RT}{F} \right) \tag{44}
\]

The displacement is to \(-30 \text{ mV}\) at 302 K when the sweep rate is increased by one order of magnitude and to 30 mV when the concentration of the initial species or the concentration in protons is increased by one order of magnitude. The preceding results are applicable when the proton concentration is sufficiently high to keep its concentration constant in the process. This is also the case when a buffer medium is used.

More generally, all the reactions occurring after the rate-determining step do not play any role in the kinetics and all the reactions before the rate-determining step act as a pre-equilibrium for the rate-determining step. In an unbuffered medium, a more complicated law results. This is not considered here.

### 5.2 Two-electron Process: Electron Transfer at the Electrode or in Solution

In organic electrochemistry, the ability to transfer more than one electron during a single step is impossible without a chemical reaction between the two electron transfers. This result is explained as follows. When two electron transfers occur in the same part of the molecule, adding (or removing) an electron leads to a group that is more difficult to reduce (or to oxidize) (repulsion of charge). Hence the second step will occur at a potential that is distinct from the first one and the two steps can be separated by a technique such as LSV.

This result is illustrated by the reduction potentials for a series of dinitro compounds.\(^{48}\) When the two groups are on the same phenyl ring, a separation of 300–500 mV is observed according to the position of these groups on the ring. When a saturated carbon chain is introduced this separation decreases and it must be noted that for a long chain (three or four CH\(_2\) groups are sufficient) the curve obtained is exactly the same in shape and potential as for a one-electron transfer with a double current. In fact, the two standard potentials are not equal but separated by \((RT/F)\ln 4\) as a function of the statistical factors for the two steps.

However, in many cases a first single two-electron process is observed. This is due to the influence of a chemical reaction that occurs between the two-electron steps that provides for a second step easier than the first one.

This is often the case because injection of an electron into an organic molecule increases its Lewis basicity and thus increases its ability either to capture a proton (or an electrophile) or to lose a base. On the oxidation side, removal of an electron from the molecule increases its Lewis basicity and thus increases its ability either to capture a nucleophile or to lose an acid. This explains the choice of a weakly acidic solvent for reduction (and the use of weakly basic medium in oxidation) in order to stabilize the initially formed ion radical and to yield useful chemical reactions, provided that some nucleophiles are specially added.

An example of a two-electron process is illustrated by the reduction process of anthracene in the presence of an acid (phenol) leading to dihydroanthracene in only one step\(^{49}\) (Equation 45):

\[
\text{Scheme 12}
\]

An example of a two-electron process is illustrated by the reduction process of anthracene in the presence of an acid (phenol) leading to dihydroanthracene in only one step\(^{49}\) (Equation 45):

\[
\text{An + e}^- \rightarrow \text{An}^+ (E_{1})
\]

\[
\text{An}^+ + \text{H}^+ \rightarrow \text{AnH}^+ (E_{2})
\]

\[
\text{AnH}^+ + \text{H}^+ \rightarrow \text{AnH}_2
\]

What are the possible mechanisms for this reaction, involving two-electron transfers? Often, a mechanism involving the sequence shown in Scheme 12 is postulated:

\[
\text{An} + \text{e}^- \rightarrow \text{An}^+ (E_{1})
\]

\[
\text{An}^+ + \text{H}^+ \rightarrow \text{AnH}^+ (E_{2})
\]

\[
\text{AnH}^+ + \text{H}^+ \rightarrow \text{AnH}_2
\]

**Scheme 12**

This mechanism is a succession of electron transfers at the electrode and of chemical reactions in solution. It is an \(E + C \rightarrow E + C\) (often called an ECE) mechanism.

By the fact that a two-electron transfer is obtained, the second electron transfer is easier than the first. This means that \(E_{2}^0\) is more positive than \(E_{1}^0\). The reaction, an electron transfer in solution (Equation 46):

\[
\text{AnH}^+ + \text{An}^{\ddagger} \rightarrow \text{AnH}^- + \text{An}
\]

is a disproportionation of two once-reduced species. This is displaced to the right, thus making the sequence in Scheme 13 also possible:

It appears that three limiting kinetic behaviors are possible, leading to characteristic variations within the experimental parameters (Table 4).\(^{50,51}\)
As is easily explained by the fact that the same reaction is the rate-determining step, the first two mechanisms are not easily separable by electrochemical techniques and under pure kinetic conditions (as in Table 4) it is impossible to deduce this determination. Yet at the level of the transition between the two-electron process and the one-electron process when the effect of the chemical reaction is increasingly weakened, some discrepancies appear between these two mechanisms. For example, in DSC, the law of variation with respect to inversion time is given in Figure 13.

It is also possible to predict what the mechanism followed is according to the values of the kinetic constants of the two reactions and according to the method used. In LSV (Scheme 14) the two parameters governing the competition between these three mechanisms are $k_d/k_1$, the equilibrium constant $K = [B]/[C]$ and $p = k_dC^0(RT/Fv)^{-1/2}(k)^{-3/2}$, where $k = k_1 + k_2$.

\[
\text{B} \xrightarrow{k_1} \text{C} \\
\text{B} + \text{C} \xrightarrow{k_d} \text{D} + \text{A}
\]

Scheme 14

Figure 14 shows the predicted kinetic control diagram. From this diagram and taking into account that the value of $k_d$ is very high since the equilibrium has been displaced toward A + D, and therefore can reach the diffusion limit in the solvent, it is possible to show that a second-order disproportionation mechanism is only possible in the case where an equilibrium B/C is displaced towards B and where $k_2$ has very high values. An ECE mechanism is often written in the case of a two-electron mechanism without a real proof of the mechanism. It appears that this case is mainly possible for an equilibrium displaced towards C and where the values of the kinetic constant $k_1$ are high. At a moderate sweep rate of 1 V s\(^{-1}\) at a millimolar concentration, if the disproportionation is at the diffusion limit ($\sim 10^{10}$ s\(^{-1}\)), the value of $k_1$ must be higher than $2 \times 10^5$ s\(^{-1}\). This is explained qualitatively by the fact that if the reaction $B \rightarrow C$ is fast the production of $C$ occurs near the electrode and the second transfer can take place another time at the electrode. However if the reaction is slow, the production of $C$ takes place far from the electrode and the solution reaction of electron exchange becomes predominant.

### 5.3 Redox Catalysis

From a practical point of view, e.g. in order to avoid passivation of the electrodes, or for kinetic purposes, it is

DISP 1 and 2 represent first- and second-order disproportionation, respectively.
Figure 14 Two-electron process. Kinetic zone diagram showing the possibilities for the three mechanisms; $p = k_3C^0(\frac{RT}{Fv})^{-1/2}(k)^{-3/2}$.

sometimes possible to realize an electrochemical reaction via the intermediary of a homogeneous electron transfer from a mediator acting as an electron carrier from the electrode to the solution.

The principle of this process is described in the example of a reductive first-order E + C reaction scheme (Scheme 15):

Direct electrochemical process:

\[ A + e^- \rightarrow B \]

\[ B \rightarrow C \]

Mediated process:

\[ P + e^- \rightarrow Q \left( E^0_{pq} \right) \]

\[ Q + A \rightarrow B + P \]

\[ B \rightarrow C \]

Scheme 15

The mediator couple (or catalyst couple) is chosen not to undergo any chemical reaction alone. Species P and A are only initially present at concentrations $C^0_P$ and $C^0_A$. It is possible to obtain a mediated process at a potential where the direct process is not operative. This would be true when the direct process is kinetically slow, that is, either when the intrinsic rate constant is low and/or if the kinetic constant $k$ is large.

Two limiting behaviors are reached according to the values of the kinetic constants and the parameters of concentration and diffusion rate. Thus, in LSV the system depends upon three parameters (Equations 47–49):

\[ \lambda_1 = k_1C^0_P \left( \frac{RT}{Fv} \right) \]  
(47)

\[ \sigma = \frac{k}{k_2C^0_P} \]  
(48)

\[ \gamma = \frac{C^0_A}{C^0_P} \]  
(49)

Two limiting behaviors are distinguished accordingly the value of $\sigma$. When $\sigma \gg 1$, the reaction of homogeneous electron exchange in the direct direction is the rate-determining step and the observed curve is a function of $\lambda_1$ and $\gamma$. An example of a curve and peak current evolution is presented in Figure 15(a–c). It must be noted that for large values of $\gamma$, a plateau-shaped curve is obtained for a wide range of values of $\lambda_1$. When $\sigma \ll 1$, the important parameters are $\lambda_1\sigma \left[ = (kk_1/k_2)(RT/Fv) \right]$ and $\gamma$. It is interesting that as the parameter is experimentally varied by changing the mediator concentration, it is therefore possible, under favorable circumstances, to shift the kinetic control from the homogeneous forward reaction to an intervention of the deactivation of B by decreasing the concentration of the mediator. This fact is used to determine the rate constant $k$ in the range $10^6$–$10^9$ s$^{-1}$, out of reach of all direct electrochemical techniques, even the most modern ones.

Another possible catalytic process, called chemical catalysis, is obtained when an adduct is formed between the catalyst (or a species obtained by electron transfer from the catalyst) and the substrate. The reaction induced by this adduct leads to the products and to a regeneration of the catalytic species after several steps and perhaps after several electron transfers. The shape of the voltammetric curves obtained in these cases can be explained by a sequence of chemical and electrochemical reactions.

6 EXAMPLES OF MECHANISM ANALYSIS AND RATE CONSTANT DETERMINATION

The ability to reduce or to oxidize electrochemically organic molecules has been the topic of numerous books and even series of books. It is not the purpose of this article to study in detail the possible reactions for each class of compounds. In many cases, the mechanism is only described by the overall reactions leading from the substrates to the products. These products are analyzed using traditional methods of organic chemistry.

We present here only a selection of some important electrochemical reactions where the mechanism is analyzed by means of electrochemical methods, leading in some cases to the determination of kinetic constants.
6.1 Kolbe Reaction

This first example deals with the oldest electrosynthetic process in organic chemistry. In an aqueous alcoholic medium without any particular precautions, salts of organic acids by oxidation undergo a decarboxylation and then the formation of a carbon–carbon bond between the two organic groups \(1,2,55\) (Equation 50):

\[
2R-\text{COO}^- \rightarrow R-R + 2\text{CO}_2 + 2e^- \quad (50)
\]

This reaction is often used with long-chain carboxylates. At the level of the mechanism determination this reaction is very difficult to analyze because these salts are difficult to oxidize and furthermore the solvents are oxidized in the same range of potential. Two kinds of mechanisms have been postulated for the oxidation of these compounds:

- radical–radical coupling leading to a dimer compound after a one-electron transfer (Scheme 16):
- the formation of a carbocation after a two-electron transfer leading to several kinds of compounds such as esters, alcohols and ethers.

\[
\text{R-} + \text{COO}^- \rightarrow \text{R}^+ + \text{CO}_2 + e^-
\]

\[
2\text{R}^+ \rightarrow \text{RR}
\]

Scheme 16
These results are supported by the analysis of the products obtained after electrolysis taking into account the structure of the carboxylate and the nature of the solvent.

However, information about the first step of the reaction or about the rate of dimerization of the two radicals is very difficult to obtain in most cases. In terms of the possibility of detecting the intermediate RCOO\(^\cdot\), nothing was possible through electrochemistry for aliphatic or for unsubstituted aromatic carboxylates and the observation of a slow electron transfer prevents further kinetic determinations. For example, it is not possible to say either that the departure of CO\(_2\) is concerted with the electron transfer or that it occurs in a second step. Even in a nonaprotic medium for easily oxidizable compounds such as aryl acetates an answer is not possible owing to the grafting process on the electrode, except in the case of the oxidation of N-dimethylaminophenyl acetate where a sweep rate of 20 V s\(^{-1}\) \(\) led to a fully chemically reversible curve in CV.\(^{56}\) In this last case the first two steps of the reaction are as shown in Scheme 17.

6.2 Reduction of Halo Compounds

These studies are conducted in an aprotic medium such as acetonitrile or DMF, and from the comparison of the heterogeneous and homogeneous electron transfer an accurate answer to the question could be given concerning the first steps of the reduction process according to the structure of the compounds.

For polyaromatic or easily reducible benzenic compounds bearing an electron-withdrawing group, a two-step mechanism is demonstrated by electrochemical methods or by a redox catalysis using as mediator a stable anion radical of aromatic compounds that permit the determination of the cleavage rate constant.\(^{42}\) In Table 5 some determinations of standard potential and cleavage rate constants are shown.

For simple phenyl halides or halopyridines, the two-step mechanism is not directly determined without a redox catalysis study showing kinetic control by the forward homogeneous exchange for all the catalysts used. From the determination of these rate constants and by observing the law showing the predicted activation and diffusion lines, homogeneous electron exchange can be characterized as an equilibrium and the standard potential of the aromatic halide/aromatic halide anion couple can be determined (Equation 51):

\[
\frac{1}{k_1} = \frac{1}{k_1^{\text{act}}} + \frac{1}{k_1^{\text{diff}}}
\left\{1 + \exp\left(\frac{F}{RT} \left(\frac{E_0^{\text{PQ}} - E_0^{\text{AB}}}{E_0^{\text{PQ}} - E_0^{\text{AB}}}\right)\right)\right\}
\]

(51)

where \(k_1^{\text{act}}\) is the kinetic constant under activation control, which in the vicinity of the standard potential \(E_0^{\text{PQ}}\) is approximately a straight line with a slope of half the diffusion line when the backward reaction \(k_2\) reaches \(k_1^{\text{diff}}\), the diffusion limit.\(^{57}\)

Although these results clearly indicate that the rate constant of cleavage is not measurable, the two-step mechanism is still followed (Figure 16a and b).

In contrast to aliphatic halides such as butyl halides, only the activation part of the reaction is observed in the redox catalysis of the compounds.\(^{40}\) The shape differs significantly from a straight line and the slope as compared with a reverse diffusion is less than 0.5 (Figure 16c and d). The shape of the curves obtained by direct electrochemical methods (for bromides and iodides; the chloro compounds are too difficult to reduce at the electrode) demonstrates a slow electron transfer, which is also attested by a transfer coefficient significantly less

than 0.5. In the context of the Marcus–Hush theory, this leads to a large gap between the reduction potential and the standard potential. All these results are characteristic of a concerted reduction and cleavage for the first step of the mechanism.

For bromides, the electron stoichiometry is 2, since the radical produced at the electrode is more easily reducible than the initial substrate. For example, with *n*-butyl bromide (Scheme 18):

\[
\begin{align*}
{n-C_4H_9}{\cdot} + e^- & \rightarrow n-C_4H_9^* + Br^- \\
n-C_4H_9^* + e^- & \rightarrow n-C_4H_9^- \\
n-C_4H_9^* + AH & \rightarrow n-C_4H_{10} + A^-
\end{align*}
\]

Scheme 18

For the tertiary and secondary iodides the first step yields a dimer compound and only in a second step (with a more negative potential) is the radical reduced\(^{(39)}\) (Scheme 19):

First step:
\[
\begin{align*}
t-C_4H_9^* + e^- & \rightarrow t-C_4H_9^* + I^- \\
2 t-C_4H_9^* & \rightarrow t-C_4H_9
\end{align*}
\]

Second step:
\[
\begin{align*}
t-C_4H_9^* + e^- & \rightarrow t-C_4H_9^- \\
t-C_4H_9^* + AH & \rightarrow t-C_4H_{10} + A^-
\end{align*}
\]

Scheme 19

Figure 16 Forward homogeneous electron exchange in the redox catalysis of halo compounds. (a) Bromobenzene; (b) 2-bromopyridine; (c) *sec*-butyl bromide; (d) *tert*-butyl bromide.
From these results, it is possible to estimate the standard potential of the anion radical–anion couple for sec-butyl (−1.4 V vs SCE) and t-butyl (−1.5 V vs SCE).

6.3 Organic Electrodimmerization

This reaction is a powerful method for the industrial preparation of adiponitrile resulting from the reduction of acrylonitrile

\[ \text{CH}_2=\text{CHCN} + 2e^- + 2\text{H}^+ \rightarrow \text{CH}_3\text{CH}_2\text{CN} \]  

(Equation 52)

In fact, this is a hydrodimerization and with this sample compound, as with many other compounds, the mechanism is very difficult to analyze owing to a reduction that is very close to the solvent reduction.

For more conjugated compounds such as p-methylbenzylidenemalononitrile in an aprotic solvent, it is possible to elucidate the sequence of reactions. One important question that arises from this reaction is how to determine whether the dimerization occurs between two reduced species [two anion radicals, EC\_\text{C}2\text{Arr} \text{][EC}2\text{Arr} \text{]} or between one reduced species reacting on the substrate [E + C2\text{Arr} \text{]}]. It is also necessary to indicate at what level the protonations by the residual water are involved.

In the present case, via LSV and via convolution, it is possible to demonstrate that the first reaction is the coupling of two radical anions followed by two protonations (Scheme 20):

\[ \text{Ph} \text{CH} = \text{CHCN} + e^- \rightarrow \text{Ph} \text{CH} = \text{CHCN} \]

\[ 2 \text{Ph} \text{CH} = \text{CHCN} \rightarrow \text{Ph} = \text{CH} = \text{CHCN} \]

\[ k_d = 10^7 \text{M}^{-1} \text{s}^{-1} \]

**Scheme 20**

The same kind of mechanism occurs during oxidation for the coupling of two cation radicals and during the oxidation of aromatic amines, the loss of proton occurring in a second chemical step.

It is possible to obtain mixed coupling when two compounds are electroactive in the same range of potential and also to obtain intramolecular coupling, yielding cyclic compounds.

The formation of electroactive polymers with compounds such as pyrrole and thiophene is an important electrosynthetic process. As the formation of long-chain oligomers is described, it has often been postulated that the propagation mechanism is the result of the addition of a cation radical or of a deprotonated radical to the monomer or to the polymer moieties. However, for example, polypyrrole is obtained as a long-chain insoluble product and even the use of the fastest method in the electrochemistry of pyrrole does not permit any way of visualizing the intermediates.

In contrast, when substituted pyroles or bipyroles are used, it is possible to demonstrate by CV or DSC that the initial step of this polymerization is a dimerization of two cation radicals; the deprotonation steps occur consecutively (Scheme 21):

**Scheme 21**

The same mechanism was demonstrated in the polythiophene series for long-chain polythiophene (three or more units) owing to the strong reactivity of thiophenes as compared with that of pyrroles.

6.4 Chemical Reactions Induced by Electrochemistry

Electrochemistry is also used for inducing chemical reactions when these reactions are impossible or slow when unaccompanied by an activating process. Under these conditions, the electrochemical methods described earlier yield interesting results about the mechanism.

These processes can be induced electrochemically without any addition of other compounds (only by some change in the oxidation degree of one reactant) or with the addition of some chemical catalysts. In the first case the process can be described by Scheme 22.

**Scheme 22**

The “zero-electron” reaction is a nucleophilic substitution induced by electrochemistry when the reduction of AY leads to the replacement of the Y substituent by L, which leads to the reoxidation of AL\_\text{[L]} in AL\_\text{[L]} \text{[L]}. The reaction is called an S_{RN1} reaction (first-order radical nucleophilic substitution) when a one-electron reduction is involved, e.g. in the substitution by phenoxy or
phenylthio groups in halo compounds (Equation 53):

\[ RX + \text{Nu}^- \longrightarrow \text{RNu} + \text{X}^- \]  \hspace{1cm} (53)

This reaction is easily studied via CV in the absence or presence of nucleophiles as illustrated in Figure 17(a) and (b). The mechanism of this reaction and good working conditions are determined by the following observations:

- the potential of initiation is the potential of reduction of RX;
- the potential of reduction of RNu must be more negative than the potential of reduction of RX;
- the “zero-electron” is more efficient for RX compounds that give a slow cleavage reaction because the faster the cleavage, the closer to the electrode the reaction occurs.

Taking into account the preceding results about the rate of cleavage of halo compounds, polyaromatic compounds must be suitable for this process. The reduction of the radical into an anion is a competing process that must be minimized, either by using chloride rather than bromide or iodide (the cleavage is faster for bromide or iodide than for chloride) or by redox catalysis of the process that also leads to radical formation far from the electrode. On the other hand, we must avoid the possibility of atom transfer from the solvent on the radical; for this purpose, liquid ammonia would be the best solvent but we can also use DMSO or acetonitrile\(^{(65)}\) (Scheme 23):

\[
\begin{align*}
RX + e^- & \longrightarrow RX^- \\
RX^- & \longrightarrow R^- + X^- \\
R^- + \text{Nu}^- & \longrightarrow \text{RNu}^- \\
\text{RNu}^- & \longrightarrow \text{RNu} + e^-
\end{align*}
\]

\textbf{Scheme 23}

A good example is the following one shown in Equation (54):

\[ 
\begin{array}{c}
\text{O} \quad \text{C} \\
\text{O} \quad \text{Br} \\
+ \\
\text{S}  \\
\text{C} \\
\text{O} \\
\text{X} \\
\text{Br}^{-}
\end{array}
\rightarrow
\begin{array}{c}
\text{O} \quad \text{C} \\
\text{O} \quad \text{S} \\
\text{C} \\
\text{X} \\
\text{Nu}^{-}
\end{array}
\]

\hspace{1cm} (54)

In many cases the simple activation by reduction (or oxidation) of one reactant does not lead to a significant reaction. A catalyst acting by a chemical reactant on the substrate can be used. For example, in the same kind of reactions, by using palladium complexes,(66,67) some new reactions are possible. The electrochemistry can play on two registers: it is often necessary to prepare the active species at the right degree of oxidation and on the other hand the mechanism of the reaction is followed by electrochemical methods (Scheme 24).

7 CONCLUSION

In contrast to small-molecule electrochemistry, the mechanisms of organic electrochemical reactions are slightly influenced by the adsorption of reactants or of intermediates on the electrodes. Hence it is possible to determine a great number of mechanisms that involve a sequence of electrochemical reactions and homogeneous chemical reactions and to characterize the key steps of these processes.

Our aim was not to list the mechanisms of the electrochemistry of each class of organic compounds but to show what can be determined using different electrochemical methods.

Because simple electron transfer steps are rather fast for organic molecules, the chemical reactions acting before or after the electron transfers are easily characterized. Using double-step techniques, mainly CV and also RRDEV or DSC, when the follow-up chemical reactions are not too fast, it is easy first to visualize the stability of the intermediates with half-lives of about $10^{-4}$ s. Under these conditions the rate constants of these chemical reactions are accurately measured using either double-step or single-step techniques (LSV, RDEV). Recent advances in electronic devices and in the miniaturization of electrodes allow the detection of intermediates with a lower limit of the detectable half-life of a few microseconds.

Preceding reaction, catalytic reaction or multielectron reactions with the same range of half-life of intermediates are easier to study because the loss of stability of the intermediates can also be followed by the significant changes in the currents giving a clearer determination of the rate constants.

Even when intermediates cannot be detected, the nature of the chemical reactions is accurately demonstrated by the use of single-step techniques as measured by the order of the reaction owing to the possibility of changing the operational window time that these techniques afford.

Even if the limitations due to the electron transfer occur less for organic than for inorganic species, very fast chemical reactions nevertheless lead to kinetic control by electron transfer and prevent kinetic information about the chemical step from being obtained. An important question still remains regarding the fact that electron transfer and chemical reaction are either two separate reactions or only one concerted process. The kinetic behavior of each electron transfer is characteristic and leads to the conclusion that contrary to common knowledge, concerted electron transfer and chemical reaction exist in many cases.

Beyond the description of the reaction sequence, the electrochemical methods described here open up the possibility of obtaining accurate information about the elementary steps in organic chemistry and can contribute to the development of structure-reactivity relationships concerning the kinetics of both electron transfers and coupled chemical reactions.

ACKNOWLEDGMENTS

I am indebted to all the members of the Laboratoire d'Electrochimie Moléculaire who participated in the work on organic electrochemical mechanisms and whose names may be found in the reference list. The invaluable contribution of Dr Jean-Michel Savéant to this field should be particularly emphasized.

For the simulation of cyclic voltammograms, Digisim® from BAS was used.

Pulse Voltammetry

Michael T. Carter
Eltron Research Inc., Boulder, USA

Robert A. Osteryoung
North Carolina State University, Raleigh, USA

1 Introduction

Pulse voltammetry comprises a family of electrochemical methods which use a train of potential pulses and corresponding current responses to generate a current–potential curve or voltammogram. Pulse voltammetry takes advantage of the difference between Faradaic (electron transfer) and non-Faradaic (interfacial charging) processes to discriminate against background, resulting in improved S/N compared with continuous electrolysis [direct current (DC)] methods, such as CV. A variety of specialized pulse sequences, conditioning potentials and other steps can be included in the complete experimental waveform, making these methods very versatile for electrochemical studies. The applied potential required to oxidize or reduce a particular species can be used to identify it in many cases. This is particularly useful in differential methods, including SWV and DPV, which provide a peaked voltammogram. The analytical utility of pulse voltammetry, as with other voltammetric methods, comes from proportionality between concentration of redox-active species in solution and measured current.

The predominant modern techniques of pulse voltammetry are SWV, NPV, RPV and DPV. SWV is a method which combines features of the pulse method with continuous electrolysis. Strictly, “voltammetry” refers to techniques applied at solid electrodes, e.g. platinum, carbon or gold and to mercury electrodes exclusive of the dropping mercury electrode (DME), such as the static mercury drop electrode (SMDE), the hanging mercury drop electrode (HMDE) and the thin-film mercury electrode (TFME). The term “polarography” strictly applies to the DME only. Normal and reverse pulse methods at the DME, for example, will be referred to as normal pulse polarography (NPP) and reverse pulse polarography (RPP), respectively, while the corresponding experiments performed at, say, a glassy carbon (GC) disk electrode are NPV and RPV. The reader will no doubt encounter many violations of this rule and a confusing array of specialized nonstandard jargon in the electrochemical literature, but one should keep in mind that all these techniques have a common basis.

1 INTRODUCTION
2 THEORY AND OPERATING PRINCIPLES

Pulse voltammetric methods are potentially very powerful analysis tools, sometimes capable of detection limits rivaling more popular analytical methods such as atomic absorption spectroscopy. Voltammetric measurements may also provide information on the thermodynamics and kinetics of an interfacial electrochemical reaction. Information is contained in the redox potential at which an electron transfer reaction proceeds, which is often characteristic of the particular species reacting and in the current, which is a direct measure of the overall rate of the reaction and is commonly proportional to analyte concentration.

We shall concentrate on basic operating principles, which will therefore be limited to simple reversible cases to illustrate the main concepts, although common complications of which the reader should be aware are mentioned where appropriate. The reader is directed to the literature citations for additional detail.

2.1 Chronoamperometric Response to a Potential Step

Chronoamperometry, measurement of current flowing in response to a potential step as a function of time, is the fundamental experiment behind all pulse voltammetry. The most basic results for a simplified redox system are described here. For convenience, electrochemists are fond of discussing generic electron transfer reactions in terms of the O/R redox couple (Equation 1):

\[
O + n e^- \leftrightarrow R
\]  

(1)

where O is the oxidized form of the couple, R is the reduced form and \( n \) is the number of electrons transferred in the reaction. In the simplest case, O and R differ by one electron, but are otherwise essentially identical, e.g. \( \text{Fe}^{3+}/\text{Fe}^{2+} \). We also usually make assumptions that both O and R are soluble, i.e. neither adsorbs on the electrode, and that both are chemically stable on the timescale of the measurement. The experimental timescale is an important aspect of pulse voltammetry. Furthermore, the electron transfer reaction is assumed to be reversible, i.e. the concentrations of O and R at the electrode–solution interface obey the Nernst equation. Clearly, this is a lot to expect from a real system. We shall discuss caveats and exceptions to the simple case as appropriate.

2.1.1 Reversible Systems Under Diffusion Control

We shall consider a case in which the working electrode is immersed in a solution of O.\(^{1-4}\) We generally ignore the rest of the electrochemical cell, concentrating on what happens at the working electrode, which is the detector in an analytical application. It is common to speak of reduction of O to R, but the reasoning applies equally to oxidations. During the electrochemical reaction, O is converted to R at the electrode surface. This conversion depends on time-dependent phenomena such as diffusion and heterogeneous reaction rate, and so pulsed electrochemical methods are characterized by currents which vary with time. As conversion proceeds, the total analytical concentration of O dissolved in solution, denoted \( C_O^a \), is partitioned between O and R. These concentrations, denoted \( C_O \) and \( C_R \), respectively, change with time and distance from the electrode surface, with the sum of \( C_O \) and \( C_R \) equaling \( C_O^a \). Designation of concentration of O or R as a function of distance (x) and time (t) is often given in shorthand as \( C_O(x, t) \) and \( C_R(x, t) \), or some variation thereof.\(^1\)

When the electrode–solution interface is perturbed by application of a potential, denoted \( E \) (volts), and \( E \) is sufficiently extreme compared with \( E^\circ_{O/R} \), the standard formal potential of the O/R system, to drive redox Equation (1) at its maximum rate from left to right, it is common (but not necessarily always the case) that the current, usually denoted \( i \) (amperes), is controlled by diffusion of O to the electrode surface. A typical potential step traversing the \( E^\circ_{O/R} \) region and resulting current response are shown in Figure 1(a) and (b). \( C_O \) at the surface of the electrode rapidly decreases to zero after pulse application and \( C_R \) increases correspondingly, as shown in Figure 2(a). The exact concentrations of O and R at the electrode surface are fixed by the Nernst equation for a reversible reaction (Equation 2):

\[
E = E^\circ - \frac{0.059}{n} \log \frac{C_R(x = 0)}{C_O(x = 0)}
\]

(2)

where \( E \) is the applied potential, \( E^\circ \) is the standard formal potential of the O/R couple and \( C_R(x = 0) \) and \( C_O(x = 0) \) are the concentrations of O and R at the electrode surface. The term 0.059/\( n \) is \( RT/nF \) at 25 °C, where \( R \) is the gas

![Figure 1](attachment:image.png)

Figure 1 (a) A potential step experiment and (b) the resulting chronoamperometric response. \( E^\circ_{O/R} \) is the formal potential of the O/R redox couple; \( E_i \) and \( E_f \) denote initial and final values of the potential, respectively.
where $A$ is electrode area and the other terms were defined previously. Equation (3) is commonly known as the Cottrell equation. The main points to take from this are that diffusion-controlled currents decay with a \( t^{-1/2} \) dependence and they are proportional to analyte concentration.

Most pulse voltammetric experiments rely on the re-establishment of “initial boundary conditions” at the electrode surface between potential steps. Following the step from $E_i$ to $E_t$, above, returning the potential to $E_i$ (Figure 2b) drives $R$ at the electrode surface back to O. A slight concentration gradient still exists, however, since some $R$ has diffused away from the electrode surface during the step. Stirring or other modes of forced convection, as shown in Figure 2(c), or waiting for a sufficiently long time at $E_i$ are commonly used to remove residual gradients and return the interface to its initial state.

2.1.2 Charging Current

An electrochemical interface has the properties of a capacitor \(^{5} \). When an electrode in contact with an aqueous medium containing dissolved ionic species is subjected to a potential step, the ions redistribute in response to change in interfacial potential. This redistribution results in a structure called the electrical double layer. Charging of the interface can be thought of conveniently as charge separation in a capacitor (Equation 4):

\[
Q = CE
\]

where charge built up on the plates of the capacitor ($Q$, coulombs) is proportional to the potential applied ($E$) and the capacitance ($C$, farads), which depends on the dielectric properties of the medium. Experimentally, a potential step applied to the interface results in current–time behavior described by a simple $RC$ circuit (Equation 5):

\[
i(t) = \frac{\Delta E}{R_s} e^{-t/R_sC_d}
\]

where $i(t)$ is the time-dependent current, $t$ is time, $\Delta E$ is applied potential, $R_s$ is solution resistance and $C_d$ is the double-layer capacitance. Typical capacitances are of the order of several $\mu$F cm\(^{-2}\) for metal electrodes in contact with aqueous electrolytes. Charging current decays as $e^{-t}$ whereas current from a Faradaic process decays with a slower $t^{-1/2}$ dependence, as shown in Figure 3. This is an important result for pulse voltammetry because it suggests that proper timing will allow significant Faradaic current to be measured at times when charging contributions are diminished. The ability to discriminate against background processes by such an approach is one feature that gives pulse methods significantly improved S/N over DC waveforms.

2.1.3 Kinetic Complications

It is convenient to think of most electrochemical processes as reversible, since this is the simplest case conceptually.
where $k$ is the standard heterogeneous rate constant (cm$^{-1}$s$^{-1}$), the reaction rate constant when $E = E^\circ$. $C_O(0,t)$ and $C_R(0,t)$ are the concentrations of O and R at the electrode surface at time $t$, $\alpha$ is the transfer coefficient (which usually has a value of ca. 0.5) and $E - E^\circ$ is the overpotential, denoted $\eta$. Overpotential corresponds to reaction driving force (applied potential) in excess of the standard potential that must be supplied to drive the O/R conversion. The current depends on the net rate of conversion of O to R, which in turn depends on applied potential. The determination of kinetic parameters from voltammetric data has been greatly simplified by computer-assisted fitting of theory to experiment. Many modern electrochemical instruments incorporate such procedures as software options.

Many physical and chemical factors manifest themselves as slow electron transfer. Specific adsorption of ions from solution on to an electrode surface, distance requirements for electron transfer at the electrode–solution interface, chemical reactions coupled to electron transfer and adsorption of macromolecular contaminants on the electrode can all result in sluggish kinetics.

Real samples often contain species which can strongly adsorb on an electrode surface, e.g. proteins in biological matrices or humic substances in fresh water. Adsorption is often strongly dependent on the nature of the electrode material. The effect of these adsorbates is to slow the rate of electron transfer at any applied potential by increasing the distance over which this event must take place. This means that more extreme potentials must be applied to drive the reaction at a rate comparable with that observed in the absence of the blockage. Such a kinetic effect typically broadens the voltammetric wave, decreases its magnitude and shifts the wave to more extreme potentials. This has important implications for detection since it can degrade both S/N and resolution.

### 2.1.4 Surface-confined Redox Systems

While adsorption of macromolecular interferents is usually a hindrance to analytical detection, confinement of an analyte at the electrode surface by adsorption or other types of intentional confinement can actually be beneficial. Adsorption offers the opportunity to concentrate reactant at the interface and eliminate diffusion from the analytical signal. Anodic stripping voltammetry (ASV) and cathodic stripping voltammetry (CSV) both take advantage of surface effects and preconcentration of analyte to allow extremely low detection limits and high analytical sensitivity.
2.2 Pulse Voltammetry at Electrodes of Classical Dimensions

We make the distinction between ‘‘classically’’ sized electrodes, i.e. electrodes with dimensions of the order of 1–0.1 mm, and microelectrodes, having at least one microscopic dimension (i.e. <0.1 mm), because the nature of analyte mass transfer and hence current response change as the dimensions of the electrode decrease. Most common electrodes that one will encounter are the ‘‘macro’’ variety, but the use of microelectrodes, discussed in section 2.4, is increasing owing to their advantageous properties.

2.2.1 Normal and Reverse Pulse Voltammetry

The NPV\(^{(1,2,12–15)}\) waveform is illustrated in Figure 4. The electrode is subjected to series of potential steps, each originating from the same initial potential (\(E_i\)), where O is stable. The potential step duration is \(t_p\). At a point late in each step, the current is measured which is denoted by an open circle superimposed on the \(E–t\) waveform in Figure 4. The potential is then returned to \(E_i\) for a waiting period, \(t_w\). Returning the potential to \(E_i\) drives any R at the electrode surface back to O, as shown in Figure 2(b). During \(t_w\), any residual R further removed from the interface diffuses away from the electrode. It is often useful during this period to stir the solution or otherwise renew the initial boundary conditions, so that the concentration of O is everywhere equal to the original bulk concentration. If \(t_w \gg t_p\), stirring may not be necessary. Following the first step, the potential is stepped incrementally to more extreme values, \(E_i + 2\Delta E_s\), \(E_i + 3\Delta E_s\), and so forth, until \(E_f\) is reached. This sequence of evenly spaced, progressively more extreme potential steps and corresponding current measurements span the region of \(E_{O/R}\). The early steps produce no electrolysis of O to R, as shown in Figure 5(a), and so generate only background current by double-layer charging. Successive potential steps eventually perturb the concentration profile of O at the electrode surface as the step approaches \(E^o\) and currents increase accordingly. At sufficiently extreme potentials, the diffusion layer is established quickly on the timescale of the potential step and the flux of O at the electrode surface is not changed.

\[\text{Figure 4} \text{ The NPV waveform with experimental parameters. Current measurement at the end of each pulse is denoted by an open circle.}\]

\[\text{Figure 5} \text{ Origin of the NPV in a series of potential steps to various values vs } E_{O/R}. \text{ (a), (b) and (c) show potential steps to values positive of, equal to and negative of } E_{O/R}^o \text{ and the corresponding chronoamperometric trace. Plotting currents sampled at } t_p \text{ vs the step potential yields the sigmoid NPV curve (d). (Reproduced in part by permission of Marcel Dekker from W.R. Heineman, P.T. Kissinger, ‘Large Amplitude Controlled-potential Techniques’, in Laboratory Techniques in Electroanalytical Chemistry, eds. P.T. Kissinger, W.R. Heineman, Marcel Dekker, New York, Chapter 3, 51–127, 1984.)}\]
appreciably at potentials well beyond $E_{O/R}'$. The current reaches a plateau in this regime.

The NPV curve (Figure 5d) has a sigmoid shape centered around the half-wave potential, $E_{1/2}$, which corresponds to $E'$ when the diffusion coefficients of the oxidized ($D_O$) and reduced ($D_R$) forms are equal (Equation 9):

$$E_{1/2} = E' + \frac{RT}{nF} \ln \left( \frac{D_O}{D_R} \right)^{1/2}$$

(9)

For most practical circumstances, the difference between $E_{1/2}$ and $E'$ is negligible. The overall shape of the NPV curve can be cast in terms of $E_{1/2}$ and the limiting current, $i_{lim}$, at the plateau of the curve (Equation 10):

$$E = E_{1/2} + \frac{RT}{nF} \ln \left( \frac{i_{lim} - i}{i} \right)$$

(10)

A semilogarithmic plot of the rising portion of the NPV curve in the vicinity of $E_{1/2}$ should therefore have a slope of $59.1/n\text{mV at }25^\circ\text{C}$ for a reversible system. This serves as a useful diagnostic criterion for reversibility, as does an absence of dependence of $E_{1/2}$ on $t_p$. Reversibility is not necessary for analytical detection methods based on pulse voltammetry, but resolution is maximized under these conditions.

The limiting current of an NPV curve is given by Equation (3), where $t$ is replaced by the pulse time, $t_p$ (Equation 11):

$$i_{lim} = \frac{nFAD_{1/2}C}{\pi^{1/2}t_p^{1/2}}$$

(11)

$i_{lim}$ is linearly proportional to concentration, hence its analytical utility. For a fixed pulse time the simple Equation (12):

$$i_{lim} = \text{(slope)}C$$

(12)

may be used to relate signal to concentration, where the slope is $nFAD_{1/2}/\pi^{1/2}t_p^{1/2}$. Often in analysis the nature of the slope will not be important, but it will vary with electrode area and diffusion coefficient. Since limiting current is proportional to $D_{1/2}$, the dependence of $i_{lim}$ on $t_p$ can also be used to determine the diffusion coefficient of an electroactive species.

Figure 6 shows consecutive one-electron transfers (Equations 13 and 14):

$$\text{TTF} \leftrightarrow \text{TTF}^+ + e^-$$

(13)

$$\text{TTF}^+ \leftrightarrow \text{TTF}^{2+} + e^-$$

(14)

where TTF is tetrathiafulvalene (CAS 31366-25-3). This figure illustrates the NPV behavior of consecutive, simple, reversible one-electron transfer reactions. Circles denote currents measured at the end of $t_p$ and crosses denote currents prior to the pulse. These latter values can be used to assess boundary condition renewal. Deviations from zero indicate inconsistent renewal of boundary conditions. The value of $i_{lim}$ for each reaction varied linearly with $t_p^{-1/2}$. $E_{1/2}$ was essentially independent of $t_p$ for each wave, suggesting reversibility of the electron transfers.

One drawback of NPV at solid electrodes, as in Figure 6, is the time needed for proper experimental control. Follow the potential pulse, the working electrode was returned to 0 V and the solution stirred to renew the boundary conditions. Allowing 12 s for this process at each pulse took 6.6 min to acquire 33 data points. The use of renewable electrodes, such as the SMDE, can significantly speed data acquisition. Although NPV is useful for certain measurements, it is extremely slow when performed at solid, stationary electrodes. Of course, if one decreases $t_p$ then $t_w$ can be decreased commensurately.

RPV (12,14,17,18) is complementary to NPV. Typical RPV waveforms are shown in Figure 7(a) and (b). The two common variants are RPV and reverse pulse voltammetry with waiting (RPW). RPV is essentially an inverted NPV experiment, whereas RPW entails additional potential steps in the nonFaradaic region positive of $E_{O/R}'$. Like NPV, the potential waveform is chosen to span the region of $E_{O/R}'$. However, unlike NPV, the experiment
PULSE VOLTAMMETRY

Figure 7 (a) Reverse pulse and (b) reverse pulse with waiting voltammetric waveforms and relevant parameters. Points of current measurement are denoted by open circles.

The RPV curve is shown in Figure 8. A corresponding NPV trace is shown for comparison. If both forms of the redox couple are stable, the RPV curve will have a limiting current, \( i_{\text{lim,RPV}} \), equal to that of the corresponding NPV experiment. The full \( i - E \) curve is displaced on the current axis from the NPV experiment, however, because of the current that flows at \( E_i \) owing to generation of \( R \). This current, denoted \( i_{\text{DC}} \), is given by Equation (11) for a reversible redox couple where the pulse time is \( t_p \). Under ideal conditions, \( i_{\text{DC}} \) should be constant at all points in the experiment. The sum of \( i_{\text{DC}} \) and the reverse pulse current \( i_{\text{RP}} \) for electrolysis of \( R \) to \( O \) in the diffusion layer is equal to the corresponding NPV \( i_{\text{lim}} \) if all species are stable (Equation 15):

\[
i_{\text{RP}} + i_{\text{DC}} = i_{\text{lim,RPV}} = i_{\text{lim,NPV}} \tag{15}
\]

The value of \( E_{1/2} \) from RPV should equal the NPV value in the reversible case and the shape of the curve is described completely analogously to NPV.

RPV can be used to electrogenerate a species under controlled conditions and examine its stability. For example, if the value of \( t_p \) is tens of milliseconds, but the product \( R \) decays on a timescale of seconds, then NPV will behave reversibly, since \( R \) is essentially stable on the timescale of that experiment. However, in RPV, if \( R \) is generated for several seconds, i.e. long enough to allow measurable decay, a fraction of \( R \) will not be available for reoxidation during \( t_p \), resulting in a decrease in \( i_{\text{RP}} \) compared with the case where \( R \) is completely stable. Instability of \( R \) on the timescale of the RPV measurement could be probed by systematic variation of \( t_p \) from short times, where \( R \) is completely stable to long times, where significant loss of \( R \) occurs and \( i_{\text{RP}} + i_{\text{DC}} < i_{\text{NPV}} \). RPV applications have included detection of halogenated organics, determination of \( \text{OH}^- \), evaluation of stability of organometallics and characterization of chemical reactions coupled to electron transfer.

The use of RPV to evaluate the stability of an organometallic complex is shown in Figure 9(a) and (b). Here, decomposition of \([\text{Ru}^{III}(EDTA)]_2\) dimer, the product of electroreduction of a related starting material, was followed as a function of \( t_p \) (Equation 16):

\[
[\text{Ru}^{III}(EDTA)]_2 \xrightleftharpoons[k_{-1}]^{k_1} 2\text{Ru}^{III}(EDTA)(\text{OH})_2 \tag{16}
\]
Removal of electroactive [Ru$^{III}$(EDTA)]$_2$ product by Equation (16) on a timescale comparable to $t_p$ was reflected in decrease in the ratio $i_{RPV}/i_{NPV}$ as $t_p$ increased. A rate constant of 0.75 s$^{-1}$ at pH 4.8 was calculated based on this trend.

### 2.2.2 Differential Pulse Voltammetry

DPV is one of the most popular pulse voltammetric methods.$^{(1,2,3,28)}$ The DPV waveform is shown in Figure 10. Each pulse of time $t_p$ and magnitude $\Delta E_p$ is preceded by a uniform waiting time, $t_w$, as in NPV, but instead of making one current measurement at the end of $t_p$, two measurements are made. The first ($i_1$) is made at $\tau'$ just prior to initiation of the pulse and the second ($i_2$) at $\tau$ toward the end of the pulse. After the pulse is completed, the potential does not return to $E_i$, as in NPV, but is incremented by a step $\Delta E_s$, typically 1–10 mV. Pulse widths and waiting times are similar to those in NPV. In differential pulse polarography (DPP) a new drop is generated at the end of $t_p$, as discussed in section 2.3.

The output of the experiment is the difference $i_2 - i_1$ vs the base potential $E_b$, hence the name of the method. DPV yields a peaked output as shown in Figure 11(a) and (b). At the beginning of the experiment, no Faradaic current flows, so $i_2 - i_1$ is very close to zero. At the other extreme, i.e. well beyond the peak, the O/R reaction is driven at its diffusion-limited rate. Further pulses do not appreciably raise the rate beyond that driven by the base potential, so again $i_2 - i_1$ is near zero. It is only in the region near $E^\circ$ that small changes in potential between the base value and the pulse value result in large changes in current and nonzero $i_2 - i_1$.

The peaked DPV output has distinct advantages for quantitation and speciation in analytical applications. The differential nature of DPV tends to flatten sloping baselines, in addition to increasing S/N. The height of the
peak varies with pulse amplitude, $\Delta E_p^{(23)}$ (Equation 17):

$$i_p = \frac{nFAD_O^{1/2}C_O}{\pi^{1/2}(\tau - \tau')^{1/2}} \frac{1 - \sigma}{1 + \sigma}$$  \hspace{1cm} (17)$$

where $(1 - \sigma)/(1 + \sigma)$ is a function of $\Delta E_p$ and $n$. $^{(23)}$

At large pulse amplitudes $(1 - \sigma)/(1 + \sigma) = 1$ and Equation (17) reduces to Equation (11). The DPV curve has a maximum current equal to that in the corresponding NPV experiment under these conditions. Usually, the DPV peak current is smaller than the corresponding NPV limiting current, at typical values of $\Delta E_p$. The enhanced sensitivity and detection limit of DPV over NPV, as much as an order of magnitude, is not due to enhancement of the Faradaic signal but to a reduction in charging current. $^{(1)}$

Maximization of sensitivity is essentially a trade-off between larger currents obtained at large pulse amplitudes and the increased background component that accompanies it. Larger pulse widths also broaden the wave, which decreases the ability to resolve multiple analytes. DPV has been used most extensively in conjunction with the DME and SMDE (section 2.3).

The peak potential, $E_p$, corresponds approximately to the NPV $E_{1/2}$. Resolution of multicomponent mixtures is defined by peak width, $W_{1/2}$, which reaches a limiting value of 90.4/n mV at 25°C, as $\Delta E_p$ approaches zero.

### 2.2.3 Square Wave Voltammetry

SWV$^{(29–39)}$ employs the waveform shown in Figure 12. Following an initial period of quiet time, $t_w$, a symmetrical train of pulses of amplitude $2\Delta E_{SW}$ is applied to the electrode, superimposed on a small DC potential increment, $\Delta E_s$, changed at a frequency ($f$) of $1/\tau$, where $\tau$ is the period of the square wave. Current is sampled at the end of each forward ($i_f$) and reverse ($i_r$) half-cycle. The difference $i_f - i_r$, called the net current, is plotted against the DC potential to yield the net voltammogram, where $i_{net} = i_f - i_r$.

SWV can be performed very quickly compared with NPV and RPV since boundary conditions do not need to be renewed before each pulse. For example, a typical square wave frequency of 50 Hz and step height of 10 mV complete a 1-V scan in 2 s, whereas the corresponding NPV experiment would take 1000 s if a 10-s waiting period was used between pulses. Measurement speed makes SWV a very promising electrochemical technique for applications including chromatography detectors and on-line monitors where real-time data acquisition may be necessary. $^{(40,41)}$

The differential nature of SWV imparts enhanced S/N and sensitivity. SWV is more sensitive than DPV by as much as 24% under optimum conditions since it uses signals from both the forward and reverse reactions in the output, whereas DPV only uses the forward component. Noise is reduced because charging components in the forward and reverse half-cycles are nearly identical, and are zeroed in the calculation of $i_{net}$.

Figure 13 shows a calculated reversible SWV curve with forward, reverse and net currents. Here the current is given as $\psi$ vs $n(E - E_{1/2})$, which are simply dimensionless variables which correspond to current and potential.

![Figure 12](image-url)  
**Figure 12** The SWV waveform and associated experimental parameters.

![Figure 13](image-url)  
**Figure 13** Calculated square wave voltammograms for (A) forward, (B) reverse and (C) net currents in dimensionless units. (Reproduced by permission of The American Chemical Society from J.J. O’Dea, J. Osteryoung, R.A. Osteryoung, ‘Theory of Square-wave Voltammetry for Kinetic Systems’, *Anal. Chem.*, 53, 695–701 (1981).)
respectively. The peak current of a reversible SWV curve is given by Equation (18):\(^{(29)}\)

\[
i_p = \frac{nFAD}{\pi^{1/2}(p)^{1/2}} \cdot \psi_p
\]  

(18)

where \(\psi_p\) is the dimensionless current function for SWV, which depends on \(nE_{SW}\) and \(n\Delta E_c\). Values of \(\psi_p\) have been tabulated.\(^{(29)}\) The peak height of the net voltammogram depends linearly on \(f^{1/2}\) for reversible systems. The peak height of a DPV curve is approximately the same as that of the forward SWV component.

The width at half-height for a reversible system is 90.5\(n\) mV, at 25 °C, for small values of \(E_{SW}\). The height and width of the wave both depend on \(E_{SW}\). For analytical applications, the peak width-to-height ratio is maximized using \(nE_{SW} = 50\) mV.\(^{(27)}\) Table 1 summarizes typical ranges of experimental parameters for commonly used pulse voltammetric methods.

### 2.3 Pulse Polarography and Voltammetry at Mercury Electrodes

Mercury electrodes have played an important role in the development of electroanalytical methods and are still used today.\(^{(42, 43)}\) The ease of oxidation of Hg in aqueous media limits its use at positive potentials. Nonetheless, Hg is an excellent material for the electrochemical detection of species with fairly negative redox potentials and for the detection of metal ions in particular. Hg also has an advantage over solid electrodes that the electrode surface can be renewed during an experiment by replacing an old drop with a new one. This is particularly useful in situations where the electrode surface may be degraded or fouled during the measurement. Recent advances in renewable mercury electrodes have been reviewed.\(^{(44)}\)

#### 2.3.1 Dropping Mercury Electrode

The DME was the original working electrode of polarography. A DME is a gravity-fed device in which Hg flows from a reservoir through a narrow-bore glass capillary having an inner diameter of the order of 0.1 mm. Hg drops form at the open end of the capillary, grow and finally fall from the capillary tip. Hg drops extruded from a capillary tip are spherical and their size generally falls in the macroelectrode range. The rate of drop formation and growth is dependent upon the height of the Hg reservoir above the tip and the diameter of the capillary. The ultimate size of the Hg drop formed depends on the surface tension between the drop and the surrounding aqueous medium into which it grows. A “drop knocker” is often used to dislodge mechanically the drop at a fixed point during growth, i.e. at constant surface area. Prior to the advent of pulse methods, continuous measurement of current was performed during the entire cycle of drop birth, growth and removal. Since the surface area of the electrode increased during the drop’s lifetime, periodic current oscillations and low S/N were facts of life for polarographic methods. Developments in pulse voltammetry addressed this problem by timing potential application and current measurement to the cycle of the DME.\(^{(1, 23)}\) The basic strategy for pulse timing, e.g. in DPP, was to apply pulses and measure currents at the very end of a drop’s life, so that surface area changes between measurements were minimized. This was possible using short pulse widths, 10–100 ms, which allowed the experiment to be performed under nearly constant electrode area conditions. Significant reduction in charging current was also realized.

</table>

\(^{a}\) Ranges indicate order of magnitude for various parameters. Drop times for Hg electrodes have not been included in the table but are typically of the order of 1–5 s.

\(^{b}\) RPV consists of two different methods, reverse pulse (RP) and reverse pulse with waiting (RPW).
Figure 14 Experimental SWV of Cd²⁺/Cd(Hg) in 0.1 M HCl for 8.43 × 10⁻³ M Cd²⁺ at a single drop (t_d, 2 s) of a DME. (a) Net current. (b) Forward and reverse currents. \( \Delta E_s = 5 \text{ mV}; E_{sw} = 30 \text{ mV}; f = 30 \text{ Hz} \). (Reproduced by permission of The American Chemical Society from J.A. Turner, J.H. Christie, M. Vukovic, R.A. Osteryoung, ‘Square-wave Voltammetry at the Dropping Mercury Electrode: Experimental’, Anal. Chem., 49, 1904–1908 (1977).)

An example of SWV at a DME is given in Figure 14(a) and (b). Here, the redox reaction is (Equation 19):

\[
\text{Cd}^{2+} + 2e^- \rightleftharpoons \text{Cd(Hg)}
\]  

in which aqueous Cd²⁺ (CAS 10022-68-1) is reduced by 2e⁻ to Cd metal, which dissolves into the Hg electrode. The entire SWV scan was performed on a single Hg drop after it had grown for 2 s. Drop surface area growth was compensated by normalizing currents to \( t_d^{2/3} \), where \( t_d \) is the drop time, since the drop surface area changes with \( t_d^{2/3} \). Today, the DME is mostly of historical interest.

2.3.2 Static Mercury Drop Electrode

The SMDE was developed by EG&G Princeton Applied Research (PAR) to address the problem of time-dependent electrode surface area and is still in widespread use today. This device can be used in either a repetitive mode analogous to the DME or as an HMDE where a single drop is used for an entire experiment. The HMDE is a spherical, stationary mercury electrode. The SMDE shares some characteristics of the DME in that it retains the Hg reservoir and uses a capillary tip to form the Hg drop.

When the SMDE is used in repetitive mode, Hg drops are extruded from the end of the large bore capillary by activation of a solenoid and plunger which prevents Hg flow when closed. When opened Hg flows, rapidly forming a drop. Deactivation of the solenoid closes the plunger and Hg flow ceases. The drop is grown to its final size and surface area very quickly compared with the DME. After a predetermined time, the drop is dislodged and the cycle repeated. Advantages realized by a renewable electrode are countered somewhat by accumulation of large amounts of waste mercury generated by the SMDE.

NPV and RPV of Fe³⁺/Fe²⁺ (CAS 10025-77-1) and Pb²⁺/Pb(Hg) (CAS 10099-74-8)/(CAS 7439-92-1) at an SMDE are shown in Figure 15. For Fe³⁺/Fe²⁺, RPV was performed starting at \(-0.5 \text{ V vs } \text{SCE}\) to generate Fe³⁺. Pb was generated at \(-0.8 \text{ V vs } \text{SCE}\). The SMDE drop grew for 1.5 s at the initial potential, \(0 \text{ V (Fe}^3+\text{)}\) or \(-0.3 \text{ V (Pb}^2+\text{)}\), prior to the RPV run. Figure 15 shows that spherical diffusion complications were apparent for RPV of Pb²⁺/Pb(Hg), i.e. \( i_{RP} + i_{DC} > i_{NP} \), when Pb dissolved in the Hg drop.

Figure 15 Normalized NPV and RPV of 0.639 mM Fe³⁺ in 0.1 M sodium oxalate–0.1 M NaClO₄ and 0.488 mM Pb²⁺ in 0.5 M acetate buffer (pH 4.8) at an SMDE. (Reproduced by permission of The American Chemical Society from T.R. Brumleve, J. Osteryoung, ‘Spherical Diffusion and Shielding Effects in Reverse Pulse Voltammetry’, J. Phys. Chem., 86, 1794–1801 (1982).)
but were absent for \( \text{Fe}^{2+/3+} \) where neither oxidation state was soluble in Hg.

2.3.3 Thin-film Mercury Electrode

TFMEs are fabricated by plating Hg on solid substrate electrodes such as carbon, platinum or gold. TFMEs allow the use of Hg in a convenient, planar format when the use of Hg drop electrodes is not practical. Such applications could include chromatographic flow cell detectors and monitors for flowing streams. The TFME is not renewable, but imparts the cathodic advantages of Hg to a detection scheme.

Pulse voltammetry has been carried out at TFMEs in DPV\(^{47,48}\) and SWV modes\(^{49–52}\) TFMEs have been shown to improve the analytical detection limit, sensitivity and resolution compared with Hg drops, particularly in ASV discussed in section 4.2.1, by virtue of exhaustive removal of electrodeposited material, which often is not achieved with a mercury drop.

2.4 Pulse Voltammetry at Ultramicroelectrodes

Ultramicroelectrodes (UMEs) have proven useful in electroanalytical pulse voltammetry. Once at the cutting edge of electrochemical research, UMEs are now fairly standard devices. A variety of geometries have been characterized, including disks, rings, bands, cylinders and arrays of these.\(^{53}\) UMEs have been prepared from solid electrode materials such as Pt, Au and C. Hemispherical Hg drop UMEs have also been fabricated. We shall discuss the characteristics of UMEs that make them useful in electroanalytical work and illustrate these points with examples of pulse voltammetric applications.

UMEs are small, with at least one microscopic dimension. An ultramicrodisk electrode, for example, may have a diameter of 20 \( \mu \)m or less. An ultramicroband electrode, on the other hand, could have a width of 20 \( \mu \)m and a length of 1–2 mm. Small physical size makes the UME obviously useful in sampling small volumes and restricted spaces. Since UMEs have a small surface area, the current flowing at them is also small. This characteristic tends to reduce the effects of uncompensated resistance (\( iR_u \)) in the electrochemical cell\(^{54,55}\) and allows undistorted voltammetry in media or physical vicinities of high resistance, e.g. a nonaqueous solvent or a very thin flow channel. UMEs feature reduced double-layer capacitance compared with larger electrodes and have smaller \( RC \) time constants which allow faster electrochemical measurements (microseconds or less) to be performed compared with their macroscale brethren.

The nature of diffusion of electroactive species to a very small electrode is different from that of its conventional counterparts. Generally UMEs show enhanced mass transfer in the form of significant radial diffusion contributions in addition to planar diffusion. This feature actually simplifies and speeds NPV and RPV experiments by eliminating the necessity for convection to achieve boundary condition renewal, and enables true steady-state limiting currents to be obtained.

SWV,\(^{55,56}\) NPV and RPV\(^{57–68}\) have been studied extensively at microelectrodes in both their theoretical and experimental aspects. Hg-based microelectrodes have also been characterized.\(^{69–71}\) Reduced \( iR_u \) at microelectrodes has allowed pulse voltammetry to be applied to resistive media\(^ {67,68}\) and media with high concentrations of electroactive species.\(^ {70}\) The small \( RC \) time constant of microelectrodes has enabled fast pulse voltammetry on the microsecond timescale.\(^ {62,64}\) Radial diffusion contributions allow rapid renewal of initial boundary conditions in the NPV/RPV experiment.\(^ {57,58,63}\)

Radial diffusion contributions to mass transfer at a microdisk electrode have important implications for the timescale on which NPV/RPV experiments can be performed. A stationary 5 \( \mu \)m radius microdisk electrode, for example, has been shown to have a mass transfer coefficient comparable to that which would be obtained by rotating a conventional size electrode at 10 000 rpm.\(^ {57}\) Simply stated, this means that it is only necessary to wait sufficiently long during \( t_w \) for re-establishment of initial conditions. If \( t_p/t_w \leq 0.1 \), initial boundary conditions can be restored without stirring for electrode diameters up to 25 \( \mu \)m.\(^ {57}\)

Figure 16(a–f) shows RPV curves taken in the RPW mode for oxidation of 5 mM \( \text{Fe(CN)}_6^{4–} \) (CAS 14459-95-1) in 0.4 M \( \text{Sr(NO}_3)_2 \).\(^ {57}\) The curves show variation of \( t_p \) between 0.01 and 5.00 s for a constant \( t_w \) of 5 s. The magnitudes of \( i_{dc} \) and \( i_{RP} \) were within 15% of theory even though no stirring was used to renew the boundary conditions.

### 3 INSTRUMENTATION AND OPERATION

This section covers some basic considerations in carrying out pulse voltammetry experiments in the laboratory. The advent of widely available commercial benchtop instruments controlled by PCs has greatly simplified the implementation of pulse voltammetry in the laboratory. It has also virtually eliminated the need to construct one’s own potentiostatic instrumentation. User friendliness has reached the stage where practically anyone can set up and use electrochemistry as a research tool. The reader will find much helpful information about the particulars of doing specific electrochemical experiments in the volumes by Heineman and Kissinger\(^ {52}\) and Sawyer and Roberts,\(^ {53}\) both of which have been updated in new editions within the past few years. With the
appearance of microprocessor-controlled potentiostats in the early 1980s, the potential of analytical voltammetry as a working tool has increased significantly. Modern Windows®-based graphic user interfaces have made many sophisticated electrochemical techniques available to a wider spectrum of users from diverse disciplines.

### 3.1 Commercial Instrumentation

We mainly discuss commercially available instrumentation from US manufacturers and among these only several representative examples. A recent review of electrochemical literature by Anderson et al. lists many useful Web sites for electrochemical instrument vendors. The reader is directed to these sources for additional information.

PAR (http://www.egginc.com) has long been a leading manufacturer of electrochemical instruments. PAR offers a line of no less than nine different potentiostat models, the most prevalent of which is probably Model 273A, which is scheduled to be discontinued. Its replacement is Model 283. Most PAR potentiostats are computer controlled from a Windows® environment. PAR offers two highly sophisticated software packages, M250 and M270, which allow the user to employ a wide array of electrochemical methods and exercise advanced data acquisition and analysis including curve fitting for mechanism and kinetics. All of the popular pulse voltammetric methods discussed in this article are represented. Two units targeted for analytical applications are the Model 394 Electrochemical Trace Analysis System and the Model 264B Polarographic Analyzer, both of which

---

**Figure 16** Reverse pulse voltammograms with waiting for 5 mM Fe(CN)$_6^{4-}$ in 0.4 M Sr(NO$_3$)$_2$ at a 12.98-µm radius Pt electrode with $t_w = 5$ s and $t_o = 0.1$ s; $t_g = (a) 0.01$, (b) 0.02, (c) 0.03, (d) 0.10, (e) 1.00 and (f) 5 s. (Reproduced by permission of The American Chemical Society from L. Sinru, J. Osteryoung, J.J. O’Dea, R.A. Osteryoung. ‘Normal and Reverse Pulse Voltammetry at Microdisk Electrodes’, *Anal. Chem.*, 60, 1135–1141 (1988).)
handle NPV and NPP. Model 394 also performs SWV, DPP and DPV.

Bioanalytical Systems (BAS) (http://bioanalytical.com) markets two multi-technique, research-grade potentiostats, the 100 B/W and the CV-50 W. BAS was the first company to attempt to make electrochemical methods more transparent and user friendly with introduction of the BAS 100 in the early 1980s. These units enable a wide range of methods to be performed, including NPV, NPP, DPV, DPP and SWV. Many automatic functions are included in these instruments, such as automatic curve analysis for peak potential and current calculation and quantitation from calibration curves. BAS also sells software for fitting of electrochemical data to mechanisms.

Cypress Systems (http://www.cypresshome.com) sells a variety of electrochemical instruments ranging from models suitable for an undergraduate laboratory to full research-grade instruments. The CS-1190 and CS-1090, for example, support SWV, DPV and DPP, but not NPV and NPP.

CH Instruments (http://www.chinstruments.com) is a relatively new company that offers a full line of electrochemical instruments in three different series, Models 600, 700 and 800. Within each series a huge array of choices may be made in terms of available techniques and other system capabilities, from units that are fairly limited for specific applications, to fully capable research-grade workstations. NPV, NPP, DPV, DPP and SWV are all supported. Many models incorporate extensive data analysis and curve fitting capabilities.

ECO CHEMIE (http://www.ecochemie.nl) is a very innovative and successful vendor of electrochemical instrumentation in Europe. Their Autolab instrument is particularly useful for implementation of modern pulse voltammetric methods.

3.2 General Considerations

Basic electrochemical experiments are actually fairly easy to setup once the electrochemical instrument is available. A real experiment could involve no more than a beaker or other suitable container, a few electrodes including a reference electrode for the three-electrode potentiostat and some solutions or samples. Pulse voltammetry will also require efficient stirring which can be actuated, e.g. by a transistor-transistor logic (TTL) pulse. SMDE units are also run via the potentiostat. The books by Heineman and Kissinger and Sawyer and Roberts cited above contain ample detail on specifics of electrochemical experiments for the interested reader.

Renewal of the initial boundary conditions is probably the most important factor in the successful implementation of analytical pulse voltammetry. If one uses an SMDE, this requirement is automatically satisfied and, as we saw above, microelectrodes also satisfy the condition easily, provided that appropriate time parameters are chosen. If solid electrodes of conventional size are employed, one must ensure that adequate stirring and time to achieve quiescence are incorporated into the pulse voltammetry protocol.

Selection of the appropriate pulse voltammetric method and experimental parameters depends on the task at hand. For a laboratory researcher wanting to evaluate \( E^0 \) and diffusion coefficients for newly synthesized organometallic complexes, NPV will probably be the method of choice. The sigmoidal shape of the NPV waveform is naturally adapted to facile comparison of wave heights and half-wave potentials. For an environmental researcher wanting to determine what electroactive trace metals are present in river water samples, then a differential method such as DPV or SWV may be more appropriate because the peaked response of these techniques is more amenable to identification and quantification of components in multianalyte mixtures. Differential methods also have a certain tolerance for irreversible background electrochemical processes such as \( O_2 \) reduction. \( O_2 \) is present at ca. 25 ppm in air-equilibrated aqueous samples and is reducible at potentials where many common analytes are electroactive. In the laboratory, one may simply deoxygenate a solution with \( N_2 \) or \( Ar \), but in field applications this practice should be avoided since it adds extra steps and cost to the analysis process. Differential methods are therefore the choice if one wishes to develop a fieldable unit.

Selection of the appropriate electrode for a particular application is often extremely important since electrode materials have widely disparate properties. Which electrode material will work acceptably will depend on the particular problem to be solved. Among the solid metals, Pt and Au have been popular. Pt is harder than Au and is therefore easier to polish to a mirror finish. Both have relatively low overpotentials for \( H^+ \) reduction to \( H_2 \), which means that their use in acidic media can be problematic. Some relief from proton reduction background can be gained by using the differential methods for the same reasons as for \( O_2 \) reduction. Pt and Au both form surface oxide films at positive potentials which may interfere with some analytical applications.

Carbon electrodes, including GC and highly oriented pyrolytic graphite (HOPG), display high overpotential for \( H^+ \) reduction and are therefore useful in acidic media. Carbon is more difficult to fabricate as a micro-electrode owing to its fragility compared with common metals, but the extra effort is often worthwhile. Carbon electrodes are used extensively in aqueous and nonaqueous electrochemistry. One problem that can be encountered with carbon is the chemical nature of the electrode surface. Carbon surfaces generally are
covered with functional groups such as quinones, carboxylic acids and so forth, the presence of which can affect electron transfer reversibility for certain analytes. Electrochemical pretreatment of the electrode is often necessary to achieve repeatable results. These pretreatments change the chemical nature and distribution of functional groups on the carbon surface. The effect of pretreatment protocols is usually determined empirically for a particular problem.

Hg electrodes have a very large overpotential for H⁺ reduction, which means that they are ideal for cathodic reduction processes in acidic media. However, Hg is easily oxidized, especially in the presence of complexing anions such as Cl⁻. Therefore, one cannot very often study oxidative chemistry at an Hg electrode. In certain nonaqueous media, the anodic range of an Hg electrode can be extended to more positive values. A major drawback of Hg, aside from the negative environmental connotations involved in using this metal, is the large amount of waste Hg generated by devices such as the SMDE. One must store and either clean up or dispose of this Hg, which can be a nuisance if a large amount of activity is anticipated. Electrodes in conventional formats, such as the SMDE, are not useful for field work, but the TFME can be used in the field.

Selection of pulse voltammetric parameters, within reasonable limits, is not as critical to the success of a method as selection of appropriate technique and electrode provided that common sense is exercised. For example, if NPV of a dissolved species is being performed to determine its diffusion coefficient and the species is stable, one would not want to select \( t_w = 500 \text{s} \) to renew the initial conditions between pulses when \( t_w = 5 \text{s} \) will do. In SWV, \( \Delta E_{sw} = 1 \text{V} \) probably will not be useful since one will quickly exceed the available potential window of the aqueous medium. Values in range 25–100 mV are more useful. Common ranges of timing parameters for various pulse voltammetric methods are given in Table 1. Within these ranges, empirical adjustment of pulse amplitudes and timing can be performed to optimize the method for a particular problem, although the parameters on the shape of the resulting voltammogram are known quantitatively and exactly for the various pulse voltammetric methods, as noted in previous sections.

In general, one cannot expect more than a ca. ±1 V window for performing aqueous electrochemistry. The available potential window depends ultimately on the potential needed to oxidize or reduce the solvent, but other limiting processes, such as redox chemistry of dissolved electrolytes, usually occur prior to solvent discharge. Redox reactions occurring at potentials more extreme than the solvent limits are not generally accessible by electrochemical methods. Electrochemical processes which occur on the edge of the solvent limit, e.g., reduction of Zn(II) in aqueous media, do not typically provide reliable quantitative information unless careful background subtraction can be performed. Nonaqueous media have significantly extended potential ranges compared with water: as much as ±2 V or more.

4 APPLICATIONS AND EXAMPLES

In this section we present a variety of illustrative examples of the use of various pulse voltammetric methods for examination of problems in chemistry, analysis and monitoring. These problems range from the most basic to the most applied and hopefully will give the reader a flavor of the possibilities for using pulse voltammetry in their own work. In the course of reviewing the literature one of us (M.T.C.) found 1703 papers containing some use of pulse voltammetric methods published in the chemical literature between January 1991 and June 1998 using only a single bibliographic search source (Chemistry Citation Index, Institute for Scientific Information, Philadelphia, PA). This is an average of 227 papers per year! Examples presented here are therefore selective, but hopefully show a spectrum of uses for pulse voltammetry.

4.1 Electrochemical Studies

4.1.1 Mass Transport

A common theme in fundamental experimental studies in electrochemistry is comparison of the shape of a voltammogram with that predicted by theory. Knowledge of the shape of a voltammogram can provide significant information about the thermodynamics and rates of the electron transfer reactions, magnitudes of diffusion coefficients and coupled chemical reaction rates and equilibrium constants. The following examples show how pulse voltammetric methods have been applied to problems involving mass transport.

Steady-state pulse voltammetry at microelectrodes has been used to probe the properties of strong and weak acids, both in simple molecular form, such as phosphoric acid (H₃PO₄, CAS 7664-38-2), and in polyelectrolytes, e.g. poly(styrene sulfonate),\(^{67,73–75}\) Steady-state current for proton reduction at an 11.25-µm radius platinum microelectrode was simply described by Equation (20):

\[
i_{ss} = 4nFD \frac{C}{r}
\]

where \( i_{ss} \) is the steady-state limiting current, \( D \) is the diffusion coefficient of proton, \( C \) is the acid concentration and \( r \) is the microelectrode radius. In the case of a simple strong acid, e.g. HClO₄ (CAS 7601-90-3), the limiting current for proton reduction was controlled by the total
acid concentration and displayed variation with ionic strength consistent with the influence of ionic strength on the diffusion coefficient of proton.\(^{(72)}\) In the case of strong acids, which are completely dissociated in water, the only reaction of interest was proton reduction (Equation 21):

\[
H^+ + e^- \longrightarrow \frac{1}{2} H_2 \tag{21}
\]

However, in the case of a weak acid, such as acetic acid (CAS 64-19-7), the additional step shown in Equation (22):

\[
\text{CH}_3\text{CO}_2\text{H} \leftrightarrow_{\text{eq}} \text{CH}_3\text{CO}_2^- + H^+ \tag{22}
\]

had to be taken into account because \(i_s\) was controlled by the slower diffusion coefficient of undissociated acid rather than that of \(H^+\). This is illustrated in Figure 17, where steady-state limiting currents are compared for the strong acid \(\text{HClO}_4\) and weak acids acetic and ascorbic acid (CAS 50-81-7).\(^{(75)}\)

4.1.2 Chemistry Coupled to Electron Transfer

Pulse voltammetry has proven useful for study of chemical reactions coupled to electron transfer.\(^{(34,38,39)}\) Some of the common reaction schemes encountered in practice include slow heterogeneous kinetics, preceding chemical reaction (prior to electron transfer) and following chemical reaction. Chemical conversions are commonly denoted \(C\) and electron transfers \(E\) in the electrochemical literature. Therefore, an ECE mechanism, for example, involves an electron transfer followed by a chemical reaction whose product undergoes a second electron transfer.

In slow electron transfer, the only new parameter to consider is the rate of the heterogeneous process, which is characterized by \(k^0\), the rate of the reaction at zero overpotential and the transfer coefficient, \(\alpha\). While slow electron transfer is not coupled to chemistry per se, it is conveniently treated along with the other deviations from ideal reversible behavior.

Chemical reactions can either precede or follow an electron transfer. The voltammetric response will depend on whether the initial and final chemical forms are redox active and the rates and reversibility of the chemical steps will depend on the timescale of the pulse method. For example, in the scheme shown in Equations (23) and (24):

\[
Y \longrightarrow O \tag{23}
\]
\[
O + ne^- \longrightarrow R \tag{24}
\]

where \(Y\) is electrochemically silent (CE mechanism), one may expect that the current obtained for the reduction of \(O\) to \(R\) (Equation 23) will depend on the rate at which \(Y\) converts to \(O\) compared with the experimental timescale. Similarly, for an electron transfer (Equation 24), followed by (EC mechanism) Equation (25):

\[
R \longrightarrow Y \tag{25}
\]

the current for oxidation of \(R\) back to \(O\) when viewed by RPV will depend on the rate of Equation (25) compared with the experimental timescale. More complicated situations, such as ECE (two electron transfers separated by a chemical conversion), disproportionation, etc., with varying degrees of reversibility are also possible and are accordingly complicated to analyze.

SWV responses have been defined for many of the basic mechanistic cases.\(^{(38)}\) A well-known example of homogeneous chemistry coupled to redox reactions is electroreduction of anthracene (CAS 120-12-7) (An) in acetonitrile\(^{(65)}\) (Equations 26–28):

\[
\text{An} \Leftrightarrow \text{An}^+ + e^- \tag{26}
\]
\[
\text{An}^+ + \text{CH}_3\text{CN} \longrightarrow \text{An}^-\text{CH}_3\text{CN}^+ \tag{27}
\]
\[
\text{An}^-\text{CH}_3\text{CN}^+ \Leftrightarrow \text{AnCH}_3\text{CN}^+ + \text{H}^+ + e^- \tag{28}
\]

The radical cation generated in Equation (26) can react with nucleophilic \(\text{CH}_3\text{CN}\) to form an oxidizable intermediate. Disproportionation of the intermediates...
Figure 18 Forward and reverse square wave voltammograms with best-fit theoretical curves for an ECE mechanism. Square wave frequencies were (○) 3401, (+) 2000 and (×) 1000 Hz, with $\Delta E_i = 10 \text{mV}$ and $E_{SW} = 50 \text{mV}$. (Reprinted from M.M. Murphy, Z. Stojek, J.J. O’Dea, J.G. Osteryoung, ‘Pulse Voltammetry at Cylindrical Electrodes: Oxidation of Anthracene’, Electrochim. Acta, 36, 1475–1484 (1991), Copyright 1991, with permission from Elsevier Science.)

(Equation 29):

$$\text{An}^+ + \text{An}^-\text{CH}_3\text{CN}^+ \rightleftharpoons \text{An} + \text{AnCH}_3\text{CN}^+ \tag{29}$$

which reforms 1 mol of starting material and produces 1 mol of final product could affect the pulse voltammetric results if these conversions proceed significantly on the voltammetric timescale. Figure 18 shows, however, that the above reaction sequence was adequately explained by an ECE mechanism, i.e. the sequence of Equations (26–28), and that Equation (29) only had a small effect on the outcome.

An example of the application of RPV to the evaluation of unstable intermediates is provided by the electrochemical reduction of 1-iodoalkanes at Hg in nonaqueous solvents\(^{(68)}\) (Equations 30 and 31):

$$\text{RI} + \text{Hg} + e^- \rightarrow \text{RH}_2\text{g}_{\text{ads}} + \Gamma^- \tag{30}$$

$$\text{RI} + 2e^- \rightarrow \text{R}^- + \Gamma^- \tag{31}$$

Reduction of the iodoalkane (RI) at Hg by one electron generates an adsorbed radical (Equation 30), while two-electron reduction at more extreme potentials produces the anion, $\text{R}^-$ and $\Gamma^-$. The radical can dimerize to form $\text{R}_2$ (Equation 32):

$$2\text{RH}_2\text{g}_{\text{ads}} \rightarrow \text{HgR}_2 \tag{32}$$

and the anion $\text{R}^-$ can react with a proton donor impurity (e.g. water) to form the alkane or with the original iodoalkane to form dimer and iodide (Equations 33 and 34):

$$\text{R}^- + \text{HD} \rightarrow \text{RH} + \text{D}^- \tag{33}$$

$$\text{R}^- + \text{RI} \rightarrow \text{R}_2 + \Gamma^- \tag{34}$$

where HD is some proton donor. Figure 19 shows RPV of 2 mM 1-iododecane (CAS 2050-77-3) in pure propylene carbonate without supporting electrolyte at an Hg hemisphere microelectrode which was formed on a 12.5-µm radius Pt disk. Note how the use of a microelectrode in this highly resistive medium gives well-defined pulse voltammetric waves. This RPV experiment probed the reoxidation of products such as $\text{RH}_2^*$ and $\text{R}^-$ generated at negative potentials. Two oxidation waves were found between ca. $-0.5$ and $+1.0 \text{V}$. The magnitude of the more negative wave decreased with increasing $t_p$, suggesting that the product formed during $t_g$ at the negative limit was unstable on a timescale comparable to $t_p$. Furthermore, the ratio $i_{\text{DC}}/(i_{\text{DC}} - i_{\text{RP}})$ for the more negative wave increased with increasing RI concentration. It was suggested that this was caused by the effect of Equation (33), the rate of which would increase with increasing concentration of RI and subsequently attenuate $i_{\text{RP}}$. Additional information was obtained by examination of the effect of the negative potential limit at which the initial products were generated, shown in Figure 19. As this value was made less negative, the magnitude of both RPV waves decreased and the height of the second wave decreased at the expense of the first. This was consistent with increased rate of radical production by Equation (30) at less negative generation.

Figure 19 RPV of 2 mM 1-iododecane in propylene carbonate at various generation potentials, indicated at the left of each curve, at an Hg hemisphere electrode plated on to a 12.5-µm radius Pt disk. $t_p = 50 \text{ms}$, $t_g = 1 \text{s}$. (Reproduced by permission of The American Chemical Society from M. Ciszkowska, Z. Stojek, J. Osteryoung, ‘Pulse Voltammetric Techniques at microelectrodes in Pure Solvents’, Anal. Chem., 62, 349–353 (1990).)
potentials and shows that the radical is actually fairly long lived in the pure solvent.

4.1.3 Corrosion

The study of corrosion processes is a broad field of electrochemical research and an extremely important one. Corrosion causes billions of dollars in losses per year in failure of equipment and civil infrastructure and is becoming an increasingly pressing problem for the military in the face of tight budgets for replacement of aging equipment such as military aircraft. Unfortunately, real corrosion phenomena are extremely complex and very difficult to simulate or reproduce in the laboratory.

Pulse voltammetry has been applied to the study of some extremely simple corrosion systems including anodic dissolution of copper (CAS 7440-50-8) and silver (CAS 7440-22-4). The virtue of the pulse voltammetric approach, in this case, is the ability to control precisely the potential applied to the corroding electrode and the timescale of potential application. Additionally, if metallic microelectrodes are used, as in the example below, a low current density allows high overpotentials to be investigated without significant IR distortion.

Anodization of a copper microelectrode (25-µm diameter, sealed in glass) was performed in 50% (v/v) ethylene glycol–water containing 1 M NaCl. The flat line in Figure 20 is the current just prior to pulse application. Constancy of this value is a good measure of the degree to which initial boundary conditions of the experiment are being renewed from pulse to pulse. The use of a microelectrode allowed the analysis of the entire anodic dissolution process. The slopes of semilogarithmic plots may be related to the stoichiometry and formation constants of the products formed. At low current densities (i.e., at the foot of the wave), Equation (35) was operative and generated a soluble product. At more extreme values, neutral CuCl was formed, which precipitated on the electrode.

4.2 Analysis and Detection

Pulse voltammetric methods hold great promise for analytical applications in laboratory and field monitoring instruments. Of particular importance is the ability of the pulse techniques to discriminate against background processes to produce high S/N detection methods. Coupled to microelectrodes and other technologies, these methods are sometimes capable of the identification and quantification of multianalyte mixtures with minimum or no sample preparation. Under favorable circumstances, pulse voltammetry is capable of sensitivity and detection limits rivaling or surpassing those of other common analytical methodologies. A comparison of detection limits for some of these methods is presented in Table 2.

4.2.1 Pulse Voltammetry Coupled to Stripping Analysis for Metal Detection

A large fraction of papers published using pulse voltammetric detection methods deal with metal detection in water. This indicates not only the importance of environmental metal pollution, especially heavy metals such as Pb (CAS 7439-92-1) and Hg (CAS 7439-97-6), but also the ideal fit between these problems and electrochemical detection. A wide variety of soluble toxic metal ions are addressable by voltammetric methods.

including Pb(II) (CAS 10099-74-8), Hg(II) (CAS 7783-34-8), Cu(II) (CAS 10125-13-0), Zn(II) (CAS 10196-18-6), Cr(VI) (CAS 7440-47-3), Cd(II) (CAS 10022-68-1) and As(III) (CAS 7784-34-1).

Identification and quantification of these metals are possible with a sub-part per billion detection limit in some cases. A particularly noteworthy demonstration of the capability of pulse voltammetric detection was provided by Meyer et al. for the detection of Hg at the $5 \times 10^{-12}$ M level, or ca. 0.01 ppt. This extremely low level of detection was achieved by ASV in conjunction with differential pulse anodic stripping voltammetry (DPASV) detection. The authors deposited Hg(II) from an acidic thiocyanate solution on to a GC working electrode. Unusually long deposition times, up to 40 min, were necessary to achieve the low detection limits reported. Nonetheless, this impressive demonstration of ultratrace metal detection shows how the very simple and relatively inexpensive electrochemical detection can rival or even surpass the performance of more complex and much more expensive instrumentation.

It is worthwhile digressing briefly to explain the ASV process since it is commonly employed for electrochemical metal detection. ASV involves two steps. First, metal is plated by cathodic deposition on to the working electrode at a prescribed potential and for a fixed time. This step is a preconcentration in which metal ions are removed from a dilute solution and plated as elemental metal on to the working electrode. Since the working electrode is small compared with the volume of sample, the metal is concentrated by several orders of magnitude during this step. If a mercury electrode is used, the metal may dissolve in the electrode if it forms an amalgam. To a first approximation, the longer the deposition phase, the more metal is deposited at the electrode. Stirling often accompanies the preconcentration step to increase mass transfer of metal ion to the electrode surface. Following the preconcentration phase, metal is oxidatively removed from the electrode or "stripped" by application of a positive-going waveform. While the waveforms used to strip metal are identical with those described earlier, the difference between ASV and common pulse experiments is that the metal to be oxidized is located on or in the electrode, rather than in the solution at the electrode–solution interface. This has the important consequence that (ideally) the metal is quantitatively removed from the electrode during oxidative stripping, resulting in a symmetrical, peaked current–potential curve. This is true even if a nondifferential technique such as NPV is employed. True quantitative stripping of metal is usually achieved only with TFMEs (section 2.3.3). In the majority of recent applications either DPASV or square wave anodic stripping voltammetry (SWASV) waveforms are used, because of their favorable background discriminating abilities. The peak current or charge under the stripping peak can then be calibrated back to the original metal ion concentration in the sample. If the peaks are not overlapped on the potential axis, stripping voltammetry can be used to identify individual components of mixtures. Detection limits in the single part per billion range are achievable, with care, in most cases.

CSV is a related method which also has been used extensively in metal detection. This method is similar to ASV in its detection step, but metals (or organics) are adsorbed in their oxidized forms on an electrode surface, often with the help of a complexing agent. The adsorbed metal ion is then reductively stripped from the electrode in the detection step. CSV is typically employed for metal ions which are difficult to reduce directly to metal in aqueous media, including Cr(VI), Zn(II) and UO$_2^{2+}$ (CAS 36478-76-9). CSV has also been employed widely in the analysis of organics, to be described in section 4.2.2.

Environmental trace metal analysis is becoming an increasingly important endeavor. Electrochemical methods provide a natural avenue to devices and instruments for field monitoring of metals. Stripping analysis by pulse voltammetry has played a large role in progress to move monitoring operations from the laboratory to the field. Microelectrodes and microelectrode arrays prepared by photolithographic methods, coupled to DPASV and SWASV, offer the promise of fast, sensitive, selective and perhaps disposable devices compatible with field systems.

Figure 21 illustrates the simultaneous detection of several metals in water using SWASV. The working

![Figure 21](image-url)
The electrode in this case was an array of 19 Ir microdisks, each 10 µm in diameter, overcoated with electrodeposited Hg to form microhemispherical Hg electrodes. The metal ions Zn(II), Cd(II), Pb(II) and Cu(II) were codeposited on to the Hg–Ir array at −1.4 V vs Ag/AgCl for 4.33 min prior to the SWV scan. Figure 21 illustrates how multiple metals can be identified and quantified by SWASV. The positions of the SWASV peaks on the potential axis identify the metal and the charge under the stripping peak, or equivalently the magnitude of the peak, quantifies the amount of each metal stripped, which is calibrated to the original sample concentration by use of appropriate calibration curves or tables. The extremely high S/N available by SWASV is clearly shown in Figure 21.

Figure 22 shows the use of SWASV for the detection of Pb(II) and Cd(II) in raw river water. The electrode was a 5 × 20 array of 12.2-µm diameter Hg hemispheres on 5-µm diameter Ir disks, and the detection method was SWASV. The concentrations shown in the figure amount to 60 ppt Pb(II) and 22.4 ppt Cd(II). This demonstrates again that it is possible to use SWASV to detect trace components with high S/N at levels competitive with conventional instruments which are not commonly amenable to portability and field analysis. Table 3 summarizes some representative detection strategies for toxic metal ions in water using pulse voltammetry.

4.2.2 Analysis of Organic Compounds

Pulse voltammetric detection has been applied successfully to a wide range of organic compounds of biomedical and environmental interest. Various forms of nonelectrolytic preconcentration coupled to CSV or ASV are applied to adsorb the analyte on an electrode, followed by SWV, DPV or similar detection. In some cases, selection of an appropriate potential, analogous to the deposition phase of ASV, is all that is necessary to facilitate adsorption of the analyte. Hg electrodes have proven useful in potential-dependent adsorption of organics for preconcentration prior to CSV. In some cases a reagent may be

added to effect adsorption of analyte, or the electrode itself can be modified to favor analyte adsorption. Detection limits in the 10⁻⁷–10⁻⁹ M range are achievable.

A recent review of adsorptive stripping voltammetry (AdSV) in the trace analysis of organic molecules and biomolecules tabulates detection limits and conditions for approximately 80 biologically active compounds. Many of these methods use pulse voltammetric detection because of their superior S/N and background discrimination. Additional details on specific analytical methods can be found in the reviews and monographs by Wang.

Table 4 shows a range of representative examples of CSV organic detection by pulse voltammetry.

### 4.2.3 Chromatographic and Flow Injection Analysis Detectors

Chromatography and flow injection analysis (FIA) represent mature practical application areas in which pulse voltammetry has made contributions. Electrochemical detection in high-performance liquid chromatography (HPLC), for example, has been carried out successfully for many years and commercial units are available. The typical arrangement uses constant-potential amperometry as the detection scheme, in which the detector electrode is held at a potential where oxidizable or reducible components of a mixture are detected following separation. In principle, very rapid scan pulse methods, such as SWV, should provide additional potential resolution within the timescale of a chromatographic peak, although these methods have not been implemented in commercial devices.

FIA is another relatively mature process analytical methodology in which samples are taken from a pot or pipe, injected into a flowing electrolyte and sent to a detector. Pulse voltammetric applications have been reported for ASV of metals and organics. A typical experimental set-up for FIA with pulse electrochemical detection is shown in Figure 23.

### 5 FUTURE PROSPECTS

Pulse voltammetry has been demonstrated to be useful and versatile in a variety of basic problems and applications. Further advances in instrumentation and

---

techniques will no doubt occur in the future, in addition to many more convincing demonstrations of the utility of these methods for solving chemical problems. Mating sensitive pulse detection methods with other advanced technologies will, hopefully, speed the use of these methods in solving practical problems. Exciting recent uses and possibilities of pulse voltammetric detection in environmental analysis are capitalizing on the microfabrication methods of the semiconductor industry, for example, to produce arrays of electrodes which can do what single electrodes cannot. There is clearly sufficient interest and activity to generate many new innovations and applications. The key for future progress and wide use of pulse voltammetry will be to apply the techniques, which are now relatively mature, to new problems and new disciplines, particularly the difficult ones, i.e. real samples and complex matrices in chemistry, biology and the environment.

ELECTROANALYTICAL METHODS

This article describes the in situ scanning tunneling microscopy (STM) operated at electrode–electrolyte interfaces. It is demonstrated that in situ STM makes it possible to monitor with atomic resolution a wide variety of electrode processes such as the adsorption of inorganic and organic species and the dissolution and deposition of metals and semiconductors. Owing to limitations on space, the focus is on selected topics and mainly on our own experimental results.

1 INTRODUCTION

Of the phenomena which occur at the interface between a solid and a liquid, common examples include the deposition and corrosion of metals, the charging and discharging of storage batteries, and the wet processing of semiconductor devices. Such processes, and many others of a similar nature, involve electrochemical (EC) oxidation–reduction reactions that take place at solid–electrolyte interfaces. Until recently, there had been few in situ methods available for the structural determination of an electrode surface, in solution, at the atomic level. Atomic level information had previously been acquired only via surface spectroscopic techniques under ultrahigh vacuum (UHV).

STM was immediately established as an invaluable and powerful surface analysis technique with atomic resolution in UHV. Belatedly, but assuredly, developments in STM operated at solid–liquid interfaces led to its valuation as arguably the premier technique for atomic-level surface structural investigations of chemical processes taking place at solid–liquid interfaces. It has been demonstrated that in situ STM makes it possible to monitor, under reaction conditions, a wide variety of electrode processes such as the adsorption of inorganic and organic species, the reconstruction of electrode surfaces, and the dissolution and deposition of metals and semiconductors. Several review articles on in situ STM and related techniques such as in situ atomic force microscopy (AFM) have been published. The reviews by Gewirth and Niece and the present author are the most comprehensive in terms of results obtained on various substrates of metals and semiconductors.

This article describes the current status of in situ STM. Owing to limitations on space, the focus is on selected...
2 Experimental Aspects

2.1 Principle of Scanning Tunneling Microscopy

In conventional STM operated in vacuum or air, a voltage \( V \) is applied between the substrate and tip electrodes as shown schematically in Figure 1. The tunneling current density \( i_T \) can be expressed by Equation (1) when a low-bias voltage is applied:

\[
i_T = \frac{e^2}{h^2} \frac{(2m\bar{\phi})^{1/2}}{\Delta s} \exp(-A\bar{\phi}^{1/2}\Delta s) \tag{1}
\]

where \( e \) is the charge of an electron, \( h \) is Planck’s constant, \( \bar{\phi} \) is the mean barrier height and \( \Delta s \) is the distance between the two electrodes. \( A \) is defined by Equation (2):

\[
A = 4\pi \frac{(2m)^{1/2}}{h} \tag{2}
\]

where \( m \) is the mass of an electron. As can be seen in Equation (1), the tunneling current is exponentially dependent on the width of the potential barrier (\( \Delta s \)) and the square root of the mean barrier height. This characteristic exponential dependence allows STM to achieve high resolution on the \( z \)-axis. For typical metals (\( \phi = 4–5 \text{ eV} \)) a predicted change in the tunneling current \( (i_T) \) of one order of magnitude with a change \( \Delta s = 0.1 \text{ nm} \) has been verified. If the tunneling current is kept constant to within 2\%, then the tunneling gap (\( \Delta s \)) remains constant to within 0.001 nm.

2.2 Principle of In Situ Scanning Tunneling Microscopy

The review by Siegenthaler describes a detailed comparison between various types of electric circuits to control the electrode potentials of the tunneling tip and the substrate independently using the so-called bipotentiostat. Figure 2 illustrates the apparatus for in situ STM with the four-electrode configuration and shows the EC cell. Using a bipotentiostat, the electrode potentials of the substrate [working electrode (WE) one (WE1)] and the tunneling tip (WE2) can be controlled independently with respect to a reference electrode (RE). The EC current \( (i_T) \) flowing through the substrate and the counter electrode (CE) can be monitored from the output of a current follower. The tunneling current \( (i_T) \) can be measured by the other amplifier. The potential difference between WE1 and WE2 is equivalent to the bias voltage \( (V) \) in Figure 1.

The side wall of the tip must be isolated in order to reduce the background EC current flowing through the tip. Soft glass, organic polymers, and Apiezon wax have been used. Details of tip-coating methods have been described by Siegenthaler.

2.3 Preparation of Well-defined Electrode Surfaces

As a fundamental basis for all STM studies, electrode–electrolyte interfaces must be prepared reproducibly, and methods must be established to observe these interfaces accurately. Well-defined single crystalline surfaces must be exposed to solution in order to understand
surface structure–reactivity relationships on the atomic scale. It is still difficult to elucidate EC reactions on the atomic scale using polycrystalline electrodes. Efforts have succeeded in producing extremely well-defined, atomically flat surfaces of various electrodes made of noble metals, base metals, and semiconductors without either oxidation or contamination in solution.

2.3.1 Flame-annealing and Quenching Method

A unique and very convenient way to expose well-defined clean Pt to aqueous solution was proposed by Clavilier et al. in 1980, in which mechanically exposed single-crystal Pt was annealed in an oxygen flame and quenched in pure water. They also established a method for preparing a single-crystal Pt electrode by melting a Pt wire in a flame. This technique was extended by Hamelin for Au, by Motoo and Furuya for Ir, and by us for Rh and Pd.

Figure 3 shows typical examples of a cyclic voltammogram (CV) of the three low-indexed Pt surfaces in sulfuric acid solution obtained in our laboratory. The results show that the hydrogen adsorption–desorption reaction is a very structure-sensitive reaction on the Pt surfaces, as indicated by the different shapes and peak positions for the CVs of the different crystalline faces. Although Clavilier et al. quantitatively analyzed the binding sites of hydrogen using systematically prepared stepped surfaces, more recent investigations using a CO replacement technique clearly indicated that the charges shown in Figure 3 include a significant contribution of the adsorption and desorption of sulfate/bisulfate.

Nevertheless, direct evidence to support the existence of a well-defined surface in solution was presented by us in 1990 using in situ STM. Figure 4(a) shows our first STM image of a flame-annealed Pt(111) in sulfuric acid solution. The height of each step is ca. 0.23 nm, in accord with the monatomic step height of 0.238 nm on a Pt(111) surface. The monatomic steps observed on the surface are usually located on nearly parallel straight lines or form an angle of 60°, as expected for a surface with threefold symmetry. The terraces seem to be atomically flat. Later it was shown that the terrace was composed of Pt atoms forming a (1 × 1) structure as shown in Figure 4(b). On the upper and lower terraces, the Pt(111–1 × 1) structure was clearly discerned at potentials near the hydrogen evolution reaction. The nearest-neighbor spacing and corrugation height were 0.28 and 0.03 nm, respectively.

Flame-annealed Au single crystals have been more frequently used for various studies including the potential-induced reconstruction investigated by several groups.\(^1\)\(^2\) However, it must be emphasized that the flame-annealing method can be applied only to Au, Pt, Rh, Pd, Ir, and possibly Ag.

2.3.2 Ultrahigh Vacuum Electrochemical Methods

It is well established that clean surfaces are exposed in UHV by cycles of Ar-ion bombardment and high-temperature annealing. The surface structure and composition are usually determined by low-energy electron diffraction (LEED) and Auger electron spectroscopy (AES). By using an ultrahigh vacuum electrochemical (UHVEC) system, in which a chamber for EC measurements was interfaced to a UHV apparatus, well-defined substrates can be transferred into an EC cell in a purified Ar atmosphere. This experimental procedure was successfully applied to various metals such as Pt, Au, Pd, and Rh.\(^1\)\(^2\)\(^\text{18}\) However, for some metals, such as Ni, the oxidation of the surface took place in the EC chamber before immersion of the electrode in electrolyte solutions owing to the presence of trace amounts of oxygen and water vapor.\(^1\)\(^8\) The same difficulty was encountered with Cu electrodes.\(^1\)\(^9\) It is clear that the problem of substrate oxidation of reactive metals occurring during the immersion and emersion processes is still unsolved in the UHVEC method.

2.3.3 Iodine–Carbon Monoxide Replacement Technique

It is important to note that iodine adlayers are known to protect highly sensitive surfaces of metal single crystals from oxidation and contamination in the ambient atmosphere, providing easy preparation and handling of well-defined surfaces during EC measurements.\(^1\)\(^2\)\(^\text{22}\) The iodine–CO replacement is known to be a method for exposing well-defined and clean surfaces of such electrodes as Pt and Rh in solution.\(^1\)\(^2\)\(^\text{20}\)\(^\text{21}\) The adsorbed iodine on these surfaces can be replaced by a CO adlayer. Clean surfaces are then exposed in solution by the EC oxidation of CO from the surface.

2.3.4 Electrochemical Etching Method

As described above, the flame-annealing and quenching method can only be applied to limited metals such as Pt, Au, Rh, Pd, and Ir and cannot be used for more industrially important less noble metals such as Ni, Co, Fe, and Cu, because they are heavily oxidized in the flame as well as in air. These metals are also difficult to transfer into electrolyte solutions without oxidation even by using UHVEC.

However, it was recently found that the anodic dissolution of various metals and semiconductors occurs only at the step edge under carefully adjusted EC conditions, resulting in atomically flat terrace-step structures. Although the etching method has not yet been well recognized as a promising method for exposing well-defined surfaces of various metals, we demonstrate in this article that layer-by-layer dissolution occurs on various semiconductors, such as Si, GaAs, and InP, resulting in the formation of atomically flat terrace-step structures. It was also found that the layer-by-layer dissolution occurs on various metals such as Ni, Ag, Co, Pd, and Cu.\(^7\)

3 STRUCTURE OF SPECIFICALLY ADSORBED ANIONS

The adsorption of anions such as iodide, bromide, cyanide, and sulfate/hydrogensulfate on electrode surfaces is currently one of the most important subjects in electrochemistry. It is well known that various EC surface processes, such as the underpotential deposition (UPD) of hydrogen and metal ions are strongly affected by coadsorbed anions.\(^1\)\(^2\)\(^3\) In particular, structures of the iodine adlayers on Pt, Rh, Pd, Au, and Ag surfaces have been extensively investigated using UHVEC techniques such as LEED.\(^1\) For example, the commensurate \((\sqrt{3} \times \sqrt{3})R30^\circ\), \((3 \times 3)\), and \((\sqrt{7} \times \sqrt{7})R19.1^\circ\) adlattices were found to form on the well-defined Pt(111–1 × 1) surface, depending on the electrode potential and pH of the solution.\(^2\)\(^2\) More recently, these structures were confirmed by STM in both air and solution.\(^2\)\(^4\) In contrast to Pt(111), only one phase of the commensurate \((\sqrt{3} \times \sqrt{3})R30^\circ\) structure was observed on Pd(111) and Rh(111) surfaces with in situ STM.\(^2\)\(^5\)\(^\text{26}\)

On the other hand, it has recently been recognized that iodine adlayer structures are more complicated on Au and Ag surfaces. Although several discrepancies about the iodine adlayer structure on Au(111) [I–Au(111)] are found in the literature,\(^2\)\(^7\) surface X-ray scattering (SXS) studies carried out by Ocko et al. revealed structural changes of I–Au(111) in KI solution.\(^2\)\(^8\) They found an increasing degree of compression, the so-called electrocompression, of the iodine adlattice with increasing iodine coverage and electrode potential. Instead of commensurate structures found on Pt(111), Rh(111), and Pd(111) as described above, they proposed that the iodine adlayer should be characterized as two distinct series of incommensurate adlattices, a centered rectangular phase and a rotated hexagonal phase.\(^2\)\(^8\) We have recently reported the structures of I–Au(111) in KI solution determined by both ex situ LEED and in situ STM,\(^2\)\(^7\) which agree with Ocko et al.’s SXS results.
Similar electrocompression was also found recently on Ag(111) using the LEED and in situ STM techniques.\(^{(29)}\) Our results clearly demonstrate that the complementary use of LEED and in situ STM is a powerful technique for determining atomic structures of iodine adlayers on single-crystal electrodes.

### 3.1 Iodine Adlayers on Platinum(111)

The objective of this section is to describe the potential dependence of the structure of iodine on Pt(111). Hubbard et al. have extensively investigated the structure of the iodine adlayer formed on Pt(111) in aqueous iodide solutions using the UHVEC technique.\(^{(1,22)}\) They demonstrated that the adlayer structures, mainly the commensurate \((3 \times 3)\) and \((\sqrt{7} \times \sqrt{7})R19.1^\circ\), were formed on the well-defined Pt(111–1 \times 1) surface in the double-layer potential range, depending on the electrode potential and pH of the solution. For example, in a solution containing 10 mM KClO\(_4\) and 0.1 mM KI, adjusted to pH 4 with HI, they found the \((3 \times 3)\) and \((\sqrt{7} \times \sqrt{7})R19.1^\circ\) structures in anodic and cathodic potential ranges, respectively [see Figure 4 in Hubbard et al.\(^{(22)}\)].

Although previous STM studies revealed various atomic structures on Pt in air and in solution, no direct in situ STM investigation has been carried out for the structural change expected from the results reported by Hubbard et al. However, as described in our recent paper,\(^{(30)}\) the structural transformation induced by changing the electrode potential did occur, but was surprisingly slow. Nearly perfect \((3 \times 3)\) and \((\sqrt{7} \times \sqrt{7})R19.1^\circ\) adlayers could be prepared by immersion of the electrode in a solution containing iodide ions at anodic and cathodic potentials, which is consistent with the previous result.\(^{(22)}\) However, in situ STM showed that both of the structures co-exist on the Pt(111) surface, when the clean Pt(111) electrode was immersed at potentials in the middle of the double-layer potential range. A typical example is shown in Figure 5(a), in which a \((\sqrt{7} \times \sqrt{7})\) domain can be clearly seen at the center of the image, surrounded by \((3 \times 3)\) domains. The potential-dependent structural change was directly imaged by a time-dependent in situ STM experiment. When the electrode potential was stepped to the cathodic potential limit, the \((\sqrt{7} \times \sqrt{7})\) structure was expected to appear upon consuming the \((3 \times 3)\) domains according to previous work.\(^{(22)}\) When the electrode potential was stepped after the acquisition of the image shown in Figure 5(a), the image shown in Figure 5(b) was obtained after 10 min, indicating that the interconversion between the two structures was very slow. Only a few iodine atoms marked by arrows were incorporated into the \((\sqrt{7} \times \sqrt{7})\) domain.

The above result provides direct evidence that the surface diffusion of iodine atoms is very slow on Pt(111), suggesting that the iodine atoms are attached to Pt(111) through a strong chemical bond. The initially formed structure was almost insensitive to changes in the electrode potential under our experimental conditions.\(^{(30)}\)

### 3.2 Iodine on Gold(111) and Silver(111)

Although the structures of the iodine adlayers are more complicated on Au(111) and Ag(111), in situ SXS studies by Ocko et al. revealed a series of I–Au(111)
The nearest I–I distance was smaller than that of \((\sqrt{3} \times \sqrt{3})R30^\circ\) (0.50 nm), and the entire lattice seemed to be rotated by several degrees with respect to the \((\sqrt{3} \times \sqrt{3})R30^\circ\). This type of adlattice has been denoted as rot–hex, \((\sqrt{3}r \times \sqrt{3}r)R(30^\circ + \alpha)\) by Ocko et al.\(^{28}\). It is interesting that the adlattices are furthermodulated with periodically arranged surface features. These features, namely groups of slightly elevated I atoms, are interpreted as Moiré patterns resulting from the mismatch between the adlattice and the lattice of Au(111).

The Moiré pattern can be analyzed by simulation to determine the adlattice constant.\(^{31,32}\) The STM images were simulated by computer calculation based on a simple “hard-ball contact model”. Various compression ratios (0–15% subtracted from the values for \((\sqrt{3} \times \sqrt{3})R30^\circ\)) and rotation angles \([0–5^\circ]\) from \((\sqrt{3} \times \sqrt{3})R30^\circ\) were tested. The rot–hex I–I distance obtained by this simulation varied from 0.45 to 0.43 nm and the rotation angle from 2 to 5°, the variations corresponding to the change of potential from 0.45 to 0.55 V.

We also carried out quantitative analysis of LEED patterns using a UHVEC system as described in our previous papers.\(^{27,31,32}\) A \(c(p \times \sqrt{3}R–30^\circ)\) structure was found in the potential range between −0.1 and 0.4 V, as shown in Figure 6. The variation of the adlattice constants is only along a particular direction of the Au atomic rows. As the largest value of \(p\) is equal to 3, at which the adlattice is identical with \((\sqrt{3} \times \sqrt{3})R30^\circ\), a value of \(p\) smaller than 3 signifies compression of the \((\sqrt{3} \times \sqrt{3})R30^\circ\) structure only in the direction of the Au(111) atom row. Hence the variation of \(p\) is referred to as uniaxial compression.

The lattice parameters determined by in situ STM and ex situ LEED are fairly consistent with those obtained by SXS, which is usually believed to give the most accurate values. Nevertheless, our results are consistent with those obtained by SXS, demonstrating that the complementary use of in situ STM and ex situ LEED is a powerful technique for characterizing the atomic structure of iodine on Au(111).

The same phase transition from the \(c(p \times \sqrt{3} – R30^\circ)\) to the rotated hexagonal structures was found and characterized by in situ STM and ex situ LEED for an iodine adlayer on Ag(111) in an H1 solution.\(^{29}\) Our result is consistent with that obtained using SXS carried out by Ocko et al.\(^{33}\) LEED patterns with six splitting spots were observed at potentials before the bulk formation of AgI, indicating that the rotated hexagonal structure was stable even in UHV.\(^{29}\) The iodine adlayer on Ag(111) was complicated in an alkaline solution, showing several structures including square \((\sqrt{3} \times \sqrt{3}R – 30^\circ)\) and \((\sqrt{3} \times \sqrt{3})R30^\circ,\)\(^{29}\) suggesting that there is a remarkable pH dependence of the structure of iodine on Ag(111).
3.3 Sulfate/Hydrogensulfate on Gold(111), Platinum(111), and Rhodium(111)

It has been demonstrated by several groups that in situ STM can be used to visualize adsorbed sulfate/hydrogensulfate species on Au(111), Pt(111), and Rh(111).

3.3.1 Gold(111)

An ordered structure with a \((\sqrt{3} \times \sqrt{7})\) symmetry was first observed for the adsorbed sulfate/hydrogensulfate on Au(111) in sulfuric acid by Magnussen et al., who proposed a model structure based on the assumption that the adsorbed species is hydrogensulfate, not sulfate, with a surface coverage of 0.4. More recently, Weaver et al. reported STM images with the same symmetry of \((\sqrt{3} \times \sqrt{7})\) on Au(111) as that observed by Magnussen et al. However, they proposed a possibility of incorporation of hydronium cations in the ordered sulfate adlayer by taking into account the result that the surface coverage of sulfate on Au(111) determined by chronocoulometry and radiochemical assay is 0.2. Note that this surface coverage is half of that for the structure proposed by Magnussen et al. as described above.

3.3.2 Platinum(111)

Stimming et al. found by in situ STM that adsorbed sulfate ions form the same adlayer structure as that found on Au(111). Ordered domains with \((\sqrt{3} \times \sqrt{7})\) symmetry appeared in the potential range 0.5–0.7 V vs a RHE in 0.05 M H\(_2\)SO\(_4\). As shown in Figure 3, only the (111) surface shows the characteristic butterfly peaks at potentials slightly more negative than 0.5 V. Their STM observations confirmed that the butterfly peaks are due to the adsorption and desorption of sulfate ions as indicated with the CO replacement technique by Clavilier et al. as described above. STM images obtained on Pt(111) were interpreted in terms of the coadsorption of sulfate anions and water.

3.3.3 Rhodium(111)

High-resolution STM imaging conducted on atomically flat terraces at 0.5 V in H\(_2\)SO\(_4\) readily discerned atomic features as shown in Figure 7(a) obtained near the step edges. The image areas include three terraces with monatomic steps. It is clearly seen that parallel atomic rows in each domain are located in the directions forming angles of nearly 60° or 120°. It is also recognized that individual bright spots exist very near the monatomic step. This observation strongly indicates that the entire surface of Rh(111) is almost completely covered by adsorbed sulfate ions even very near the end of the terraces.

**Figure 7** High-resolution STM images of sulfate adlayer on Rh(111) obtained in H\(_2\)SO\(_4\). (Reprinted with permission from L.-J. Wan, S.-L. Yau, K. Itaya, ‘Atomic Structure of Adsorbed Sulfate on Rh(111) in Sulfuric Acid Solution’, J. Phys. Chem., 99, 9507–9513. Copyright (1995) American Chemical Society.)
Figure 7(b) presents an STM image showing a more detailed internal structure acquired in an area where a single domain appeared on a wide terrace. It can be seen that there are two different parallel rows with a 30° rotation relative to the underlying Rh lattice. One appears as bright spots. The observed atomic distance in these bright rows along the A direction is equal to 0.46 nm. The average distance between neighboring bright rows is ca. 0.7–0.73 nm. The interatomic distance of 0.74–0.75 nm observed along the B direction in this particular STM image in Figure 7(b) is slightly larger than that of the \( \sqrt{3}a_{\text{Rh}} \) (0.707 nm), probably owing to a small thermal drift during the acquisition of the image. However, it was ascertained that the distance along the B direction is very close to the \( \sqrt{3}a_{\text{Rh}} \) based on the averaging of all atomic images obtained in this study. The angle between the directions marked by arrows A and B in Figure 7(b) is ca. 72°. The above results strongly indicate that the unit cell can be defined by the so-called \((\sqrt{3}\times\sqrt{7})\) structure. The rows along the direction marked by the arrow B are constituted of alternative bright and dark spots in the image shown in Figure 7(b). The dark spots appeared almost at the center between neighboring bright spots in the direction of B. Magnussen et al. have also found the position for the darker spots equidistant between two brighter spots along the B direction.\(^{34}\)

The results described above are almost the same as those reported for Au(111) by Magnussen et al.\(^{34}\) and other investigators\(^{35}\) and those observed on Pt(111).\(^{37}\) Magnussen et al. proposed a model structure with a unit cell, the so-called \((\sqrt{3}\times\sqrt{7})\), for the adlayer of hydrogensulfate (\(\text{HSO}_4^-\)) on Au(111). Both bright and dark spots were interpreted as hydrogensulfate ions adsorbed on Au(111). Therefore, the surface coverage of this proposed structure is 0.40.

According to the coverage value of ca. 0.2 obtained on Rh(111) by Zelenay and Wiekowski,\(^{39}\) it is reasonable to expect that only the bright spots in the STM images observed on Rh(111) correspond to the adsorbed sulfate or hydrogensulfate. If sulfate or hydrogensulfate is assumed to be also trigonally coordinated on Rh(111), a ball-model can be presented as shown in Figure 8(a), where the \(\text{SO}_4^{2-}\) (or \(\text{HSO}_4^-\)) is positioned at the threefold hollow sites. It can be seen in Figure 8(a) that the sulfate ions along the \(\sqrt{3}\) direction form an almost close-packed row. On the other hand, an open space can be found between neighboring rows of the sulfates. As described above, Weaver et al. proposed a model where coadsorbed hydronium cations exist along the \(\sqrt{3}\) direction between neighboring rows of sulfates.\(^{35}\) The dark spots which appeared in the STM images were assigned to be the coadsorbed hydronium cations. Such cation coadsorption was expected to minimize the coulombic repulsion between adjacent \(\text{SO}_4^{2-}\) on Au(111). Although the coadsorption of hydronium cations is thought to be a factor which explains the nonuniform interatomic distances of the \((\sqrt{3}\times\sqrt{7})\) structure, it is not clear why the adsorbed sulfates have the different spacings along the \(\sqrt{3}\) and \(\sqrt{7}\) directions.

In a previous paper, we proposed a new model to explain the nonuniform spacing in the unit cell of \((\sqrt{3}\times\sqrt{7})\).\(^{38}\) It can be seen in Figure 8(a) that uncoordinated Rh atoms are arranged in a zig-zag form.
in the $\sqrt{3}$ direction between neighboring rows of the adsorbed sulfates. In the new model shown in Figure 8(b), hydrogen-bonded water chains are simply inserted along the $\sqrt{3}$ direction between neighboring rows of the sulfates. The model shown in Figure 8(b) includes the adsorbed sulfate/hydrogensulfate and hydrogen-bonded water chains formed along the $\sqrt{3}$ direction. The model shows only the first water bilayer. Water molecules in the first layer are bonded directly to Rh atoms at the top site via the oxygen lone pair. For the ice-like lattices on the fcc(111) surfaces, two hydrogen bonds form to oxygen lone pairs of two water molecules in the second layer. It is assumed, however, that only a hydrogen bond forms to an oxygen lone pair of a water molecule in the second layer as shown in Figure 8(b), although it is expected that the water in the second layer forms a hydrogen bond with an oxygen lone pair of sulfate, which is not drawn in Figure 8(b) for the sake of clarity. According to the model, it is possible that the dark spots which appeared in the STM image shown in Figure 7(b) arise from the water molecules in the second layer. Although the model presented here would seem to be equivalent or similar to the model proposed by Weaver et al., we believe our model more confidently explains the feature of the nonuniform interatomic distances in the $\sqrt{3}$ structure. It is also noteworthy that the hydrogen-bonded water chains are expected to form hydronium cations in acidic solutions. If the water molecule in the second layer is protonated to form hydronium cations, the model presented here is equivalent to the model proposed by Weaver et al. We have calculated the heights of the adsorbed sulfate and the water molecule in the second layer for the model shown in Figure 8(b) using a hard-ball contact model, yielding values of 0.35 and 0.30 nm respectively. The outer sphere of the water molecule in the second layer is slightly lower than that of the sulfate. It is interesting to compare these values with the corrugation heights described above, although it is true from a theoretical point of view that corrugation heights observed in STM images should arise from electronic factors, such as wave functions of adsorbates rather than spatial structural factors. We believe that a similar coadsorption of water chains and sulfate might occur on Au(111) and also possibly on Pt(111).

The adlayer structure almost abruptly disappeared at potentials near the hydrogen evolution reaction, showing the Rh(111–$1 \times 1$) structure, indicating that the adsorbed sulfate is completely desorbed at the potential of the hydrogen evolution.

Nevertheless, it is now clear that sulfate/hydrogensulfate form adlayers with the same structure and symmetry on at least three different substrates, Au(111), Rh(111), and Pt(111). It is noteworthy that the atomic diameters of Au, Rh, and Pt are 0.289, 0.268, and 0.278 nm, respectively, i.e. the diameter of Rh is the smallest. In general, structures of many adlayers depend strongly on the diameter of substrates. The appearance of the same ($\sqrt{3} \times \sqrt{7}$) structure on the substrates with different lattice parameters might suggest that the coadsorption of sulfate/hydrogensulfate and water illustrated in Figure 8(b) is flexible with respect to the change in lattice parameter of the substrate. Such flexibility may be due to the existence of water molecules between the sulfate/hydrogensulfate chains with a relatively weak hydrogen bonding.

3.4 Cyanide

In situ STM was recently employed by Weaver et al., for the first time, to examine the CN adlayer on Pt(111). It was reported that six CN functional groups form a hexagonal ring with an additional CN in the center of the ring (see Figure 9b).

Our in situ STM observations revealed a new structure for the CN adlayer and the complexation of alkali metal cations such as Na$^+$ and K$^+$ with the CN adlayer on Pt(111). An atomically resolved STM image acquired in an alkaline CN solution containing Na$^+$ cations is shown in Figure 9(a). Figure 9(a) shows an STM image of the hollow hexagonal pattern. This image (5 $\times$ 5 nm) was acquired in 0.1 mM NaCN + 0.1 M NaClO$_4$ (pH 9.5) at 0.6 V with a bias voltage of $-50$ mV and a tunneling current of 20 nA.

Under these experimental conditions, well-arranged hexagonal rings, aligned in a direction 30° rotated from the close-packed directions of Pt(111) lattice, are observed. The 0.95 $\pm$ 0.02 nm distance between the nearest-neighbor hexagonal rings, as measured from their centers, is roughly twice as large as the $\sqrt{3}$ lattice spacing of the Pt (0.2778 nm). This ordered atomic feature can be characterized as the ($2\sqrt{3} \times 2\sqrt{3}$)$_{R30^\circ}$ structure. However, Weaver et al. reported an STM image [see Figures 3 and 4 in Stuhlmann et al.] which was interpreted as the ($2\sqrt{3} \times 2\sqrt{3}$)$_{R30^\circ}$–7CN structure with cyanides bound in symmetric top sites surrounded by hexagonal rings of near-top CN. It is important to see in Figure 9(a) that the center spots are now essentially invisible in the image, strongly suggesting that there is no cyanide in the center of the hexagonal ring.

Based on the results described above, two model structures are presented in Figures 9(b) and (c) to outline atomic arrangements of the adsorbed CN on Pt(111). The model structure shown in Figure 9(b) is essentially a replica of the model proposed by Weaver et al. in which the center spot was attributed to the adsorbed CN. However, the image shown in Figure 9(a) suggests that the adsorbed CN is not located in the center of the six-membered ring. Figure 9(c) is a new model where the adsorbed CN in the center is removed. It is interesting that the six-membered ring is similar in structure to crown ethers. Crown ethers are known
to complex effectively with alkali metal cations. The configuration of the CN adlayer is such that the C is bound to the Pt electrode with the N facing the solution side. Each nitrogen atom contains a lone pair of electrons which is expected to act as a binding site similar to the oxygen atoms in crown ethers.

It was surprising to find that the bright spots appear in the center of the six-membered ring in a solution containing K⁺ as shown in Figure 9(d). It was found that K⁺ cations are more strongly bound than Na⁺ in the center of the CN ring, because bright spots due to the coordinated Na⁺ cations were only sparsely observed in

Figure 9 (a) High-resolution STM image of the hollow CN hexagonal arrangement. Two ball models of the \((2\sqrt{3} \times 2\sqrt{3})R30^\circ\) structure are shown in (b) and (c). (d) STM image in the solution containing K⁺ ions. (Reprinted with permission from Y.-G. Kim, S.-L. Yau, K. Itaya, 'Direct Observation of Alkali Cations on Cyanide-modified Pt(111) by Scanning Tunneling Microscopy', J. Am. Chem. Soc., 118, 393–400. Copyright (1996) American Chemical Society.)
the center of the hexagonal ring of CN. Our STM result for the coordinated K⁺ described above is probably the first case to describe an outer Helmholtz layer, because almost all previous STM studies have elucidated the adlayer structure directly attached on the electrode surface.

4 UNDERPOTENTIAL DEPOSITION

The EC adsorption of hydrogen and metals on a foreign metal substrate taking place in a potential region positive to the thermodynamically reversible potential is called the UPD. Particularly the UPD of hydrogen on single-crystal Pt electrodes was intensively and systematically investigated by Clavilier et al.\textsuperscript{13} The UPD of a metal, M, on a different metal substrate, Ms, is expected to occur at potentials more positive than the reversible potential for the bulk deposition of M when an interaction between M and Ms is greater than that of Ms–Ms. The UPD process is important in EC reactions, such as metal deposition, as the initial step of a series of reactions and also because of electrocatalytic effects induced by adatoms formed by the process. Although a large number of UPD systems have been investigated using conventional EC techniques, such as CV, to evaluate the thermodynamics and kinetics, the structural information of UPD layers was first obtained mainly by Hubbard et al. using the UHVEC technique.\textsuperscript{1,2} With a considerable amount of previous knowledge available on the UPD phenomenon itself, in situ STM was applied, for the first time, to determine the structure of the adlayer of Cu on Au(111) in sulfuric acid solutions with atomic resolution.

4.1 Copper Underpotential Deposition on Gold(111)

Magnussen et al. reported the first atomic image of a Cu adlayer on Au(111) in sulfuric acid solution.\textsuperscript{42} They found a \((\sqrt{3} \times \sqrt{3})R30°\) structure after the first UPD peak which transformed into a second phase of \((5 \times 5)\) structures. However, the appearance of the \((5 \times 5)\) structure was confirmed to be due to chloride contamination,\textsuperscript{43} suggesting that the UPD process is extremely sensitive to co-adsorbates.

Figures 10(a) and (b) show CVs of an Au(111) electrode obtained in pure 0.05 M H₂SO₄ solution in the presence of 1 mM CuSO₄.\textsuperscript{44} The main oxidation peak at 1.25 V and the cathodic peak at 0.82 V are due to the oxidation of the surface of Au(111) and the reduction of the oxide layers, respectively. On the other hand, two different waves for the UPD of Cu are clearly observed in the potential region between 0.35 and 0 V vs a saturated calomel electrode (SCE) before the beginning of the bulk deposition. Figure 10(b) shows a detailed CV for the UPD observed at a scan rate \((v)\) of 1 mV s\(^{-1}\). Two distinctly different processes can be seen clearly in the CV shown in Figure 10(b). The peak current is proportional to the scan rate only up to 5 mV s\(^{-1}\), and then is approximately proportional to \(v^{1/2}\), suggesting that the UPD of Cu on Au(111) is a surprisingly slow process.

Figure 11(a) shows a high-resolution STM image obtained in 0.05 M H₂SO₄ + 1 mM CuSO₄ solution.\textsuperscript{44}
Although the wide terrace of the Au(111) surface was almost completely covered by the Cu adlayer with the \((\sqrt{3} \times \sqrt{3})R30^\circ\) structure, several types of phase boundary can be seen in Figure 11(a). Figure 11(b) shows a model structure of the phase boundary marked by arrow (a), in which two \((\sqrt{3} \times \sqrt{3})R30^\circ\) domains are shifted by a half position along the direction indicated by the arrow. In the model structure shown in Figure 11(b), it was assumed that the solid circles represent Cu atoms.

The same \((\sqrt{3} \times \sqrt{3})R30^\circ\) structure was also found by in situ AFM.\(^{45}\)

However, the coulometric curve obtained simultaneously with CV shown in Figure 10(b) showed that the ratio of the charges consumed during the first and second UPD processes was roughly 2:1, suggesting that the surface coverage of Cu was about 2/3 after the first UPD peak.\(^ {44}\) According to the model structure shown in Figure 11(b), the surface coverage must be 1/3 because of the \((\sqrt{3} \times \sqrt{3})R30^\circ\) structure.

This discrepancy was carefully investigated by Shi and Lipkowski using a chronocoulometric technique. They measured the Gibbs excess of Cu adatoms and that of coadsorbed sulfate \((\text{SO}_4^{2-})\) as a function of the electrode potential, and concluded that Cu adatoms are packed to form a honeycomb \((\sqrt{3} \times \sqrt{3})R30^\circ\) structure with the center of each honeycomb cell occupied by a sulfate ion.\(^ {46}\)

Finally, Toney et al. examined the above system using an SXS technique,\(^ {47}\) and concluded that the Cu atoms form a honeycomb lattice and are adsorbed on threefold hollow sites with sulfate ions located at the honeycomb centers. They also concluded that three oxygens of each sulfate ion bond to Cu atoms. According to all of the results described above, the most reliable model structure can be presented as shown in Figures 12(a) and (b), in which top and perspective views, respectively, are given. This model structure is essentially the same as that shown by Toney et al.\(^ {48}\) According to the model structure, the corrugation observed by in situ STM and AFM must be considered to be due to the coadsorbed sulfate ions, and not the Cu atoms. Note that Blum et al. studied a statistical mechanical model for the UPD of Cu.\(^ {48}\) Their proposed structure is similar to that shown in Figures 12(a) and (b).\(^ {48}\) The study of the UPD of Cu on Au(111) was a very important lesson for understanding limitations and strengths of various in situ techniques. It is clear that STM and AFM cannot distinguish chemical species.

Review articles are useful for finding the literature on UPD of various metals on different substrates.\(^ {6,7}\) Here we only describe the UPD of Cu on Au(111), which is the most extensively studied system.

5 ADSORPTION OF ORGANIC MOLECULES ON MODIFIED ELECTRODES

STM has also made it possible to determine directly orientations, packing arrangements, and even internal structures of organic molecules adsorbed both on surfaces in UHV and at solid–liquid interfaces. For example, individual molecules and distinguishable molecular shapes of benzene on Pt(111), coadsorbed benzene and CO on
Rh(111), naphthalene on Pt(111), and copper phthalocyanine on Cu(100) have successfully been resolved with STM under UHV conditions. These results have stimulated a large number of STM studies of ordered molecular adlayers in UHV and air and at solid–liquid interfaces.

A variety of experimental procedures have been reported for the preparation of ordered molecular adlayers on well-defined substrates including single crystals of metals and layered materials, such as highly ordered pyrolytic graphite (HOPG) and MoS₂. Alkanethiols have been intensively investigated on metals such as Au, because the −SH group is known to be chemically attached to the Au surface through the formation of a covalent bond between S and Au atoms, producing densely packed adlayers. On the other hand, it is well known that simple physical adsorption can also provide ordered adlayers of molecules, such as liquid crystals and n-alkanes on inert substrates such as HOPG and MoS₂.

From the EC point of view, the adsorption of organic molecules at electrode–electrolyte interfaces can be considered as one of the most promising approaches not only for the preparation of ordered adlayers, but also for elucidating the role of properties of adsorbed molecules and the nature of electrode–electrolyte interfaces. In spite of a large number of reports describing observations by STM and related techniques, such as AFM of adsorbed organic molecules in UHV, air, and organic liquids, only a few in situ STM studies have been carried out for organic molecules adsorbed at electrode–electrolyte interfaces under EC conditions. Recently, pioneering studies have shown high-resolution images of molecules such as DNA bases (adenine, guanine, and cytosine) adsorbed on HOPG and Au(111) in electrolyte solutions. In another study, xanthine and its oxidized form and porphyrins were found to form ordered adlayers on HOPG. Further, the order–disorder transition in a monolayer of 2,2'-bipyridine on Au(111) was reported as a function of electrode potential.

Although a number of successful in situ experiments using STM and AFM have been performed to determine the structure of organic adlayers, HOPG, similar layered crystals, and Au electrodes have almost exclusively been used as the substrate. Therefore, the role of the interaction between organic molecules on one hand and substrates on the other in ordering processes is not yet fully understood. We have long been interested in finding a more appropriate substrate to investigate the adsorption of organic molecules. Recently, we disclosed a novel property of iodine-modified electrodes for the adsorption of organic molecules. It was found, for the first time, that a water-soluble porphyrine, 5,10,15,20-tetrakis(N-methylpyridinium-4-yl)-21H,23H-porphyrine (TMPyP), formed highly ordered molecular arrays via self-ordering on the iodine-modified Au(111) electrode in HClO₄ solution. As described in the preceding section, the iodine adlayers are thought to protect metal surfaces from oxidation and contamination in the ambient atmosphere, providing an easy method of preparation of well-defined surfaces. However, it should now be recognized that the I–Au(111) electrode is one of the most promising substrates for the investigation of organic molecules in solution. Indeed, we discovered this electrode, with great generality, to be a suitable one on which to form highly ordered adlayers not only of TMPyP but also various other molecules such as crystal violet. It was also demonstrated in our papers that various iodine-modified metal electrodes such as Ag(111) and Pt(100) can also be employed as a substrate on which to investigate the adsorption of organic molecules. In this section, we briefly...
summarize in situ STM of organic molecules adsorbed on iodine-modified electrodes.

5.1 5,10,15,20-Tetrakis(N-methylpyridinium-4-yl)-21H,23H-porphyrine on Iodine–Gold(111)

The experimental procedure was fairly simple. A well-defined Au(111) surface prepared by the flame-annealing and quenching method was immersed in 1 mM KI solution for several minutes and then thoroughly rinsed with 0.1 M HClO₄ solution. The iodine-modified electrode, thus prepared, was installed in an EC cell containing pure HClO₄ solution for in situ STM measurements. Under potential control, the iodine adlayer structures can be determined by in situ STM as described above. After achieving an atomic resolution, a dilute solution of TMPyP was injected into the HClO₄ solution. After the addition of TMPyP, STM images for the iodine adlayer usually became unclear within the first 5–10 min, because of the adsorption of TMPyP, and then ordered adlayers became visible, extending over atomically flat terraces.

Molecular orientations, packing arrangements and even internal molecular structures of the adsorbed TMPyP molecules can be seen in high-resolution STM images. Two typical STM images are presented in Figures 13(a) and (b). These high-resolution images directly demonstrate that the flat-lying TMPyP molecule can be recognized in the images as a square with four additional bright spots. The shape of the observed features in the image clearly corresponds to the chemical structure of the TMPyP molecule. The characteristic four bright spots located at the four corners of a square correspond to the pyridinium units of TMPyP. The center to center distance between the bright spots was found to be 1.3 nm measured diagonally, which is nearly equal to the distance between two diagonally located pyridinium units. In addition to the internal structure, the STM image shown in Figure 13(a) reveals details of the symmetry and the packing arrangement. It can be seen that there are three different molecular rows marked by arrows I, II, and III. In the row marked I, all TMPyP molecules show an identical orientation with an intermolecular distance of ca. 1.8 nm. An alternative orientation can be seen along the row II in which every second molecule shows the same orientation. On the other hand, the rotation angle of ca. 45° can be recognized between two neighboring molecules in row III.

The well-ordered TMPyP arrays were found to extend over atomically flat terraces as shown in Figure 13(b), which was obtained in areas involving monatomic step edges. It is clearly seen that the same molecular feature as that seen in Figure 13(a) extends over the lower and upper terraces. The ordered structure could be seen even on the relatively narrow terrace in the upper part of the image. It is also surprising to find that individual TMPyP molecules exist very near the monatomic step. The result shown in Figure 13(b) indicates that the entire
surface of the I–Au(111) is almost completely covered by ordered TMPyP molecules even near the end of the terraces. Figures 14(a) and (b) illustrate a structural model showing a top view and a side view of the ordered TMPyP adlayer on the iodine on Au(111), respectively. We have also investigated the adsorption of TMPyP on a well-defined Au(111) in the absence of iodine adlayer.\textsuperscript{57} After achieving an atomic resolution for the Au(111–1 × 1) structure in 0.1 M HClO\textsubscript{4}, a dilute solution of TMPyP was injected into the solution in a manner similar to that described above. Although the TMPyP molecules adsorbed directly on Au(111) could be seen by STM, the adsorbed molecules did not form ordered adlayers. Disordered adlayers formed on bare Au(111) suggest that strong interactions including chemical bonds between the Au substrate and the organic molecules prevented self-ordering processes from occurring, which must involve surface diffusion of the adsorbed molecules. The surface diffusion of the molecules adsorbed on bare Au was found to be very slow. Relatively weak van der Waals-type interactions between the hydrophobic iodine adlayer and the organic molecules could be the key factor promoting self-ordering processes on the I–Au(111) substrate.

It should particularly be emphasized that the iodine layer plays a crucial role in the formation of highly ordered TMPyP arrays. The relatively weak van der Waals-type interaction on the iodine adlayer seems to be a key factor in the formation of ordered molecular arrays of such large molecules. However, the relationship between the TMPyP and iodine adlayer structures is not fully understood, as described above,\textsuperscript{57,58} because the iodine adlayer structures on Au(111) and Ag(111) are complicated by a potential-dependent compression in the adlayers.\textsuperscript{27,29}

### 5.2 Other Molecules on Iodine–Gold(111)

Here, we briefly describe further evidence that the I–Au(111) electrode can be employed as an ideal substrate for in situ STM imaging of various adsorbed organic molecules in solution. Organic substances investigated were water-soluble cationic molecules purposely selected based on their characteristic shapes: triangular and linear. Hexamethylpararosaniline (crystal violet) and 4,4’-bis(N-methylpyridinium)-p-phenylenedivinylene (PPV) were also found to form highly ordered molecular arrays on top of the iodine monolayer adsorbed on Au(111).\textsuperscript{56}

In situ STM with near-atomic resolution revealed their orientation, packing arrangement, and internal structure of each molecule. A typical high-resolution STM image of the molecular arrays of crystal violet (Figure 15b) is shown in Figure 15(a). It is also surprising to see that the STM image shows a distinctly characteristic, propeller-shaped feature for each molecule with highly ordered arrays. Each molecule has three benzene rings located at the apexes of a triangle with an equal distance from the central carbon atom. Three bright spots seem to correspond to the benzene rings. The center of each spot is located at a distance of ca. 0.35 nm from the center of the triangle. An additional spot can also be seen at the position of the central carbon atom of crystal violet. According to the STM image, it is clear that all molecules are oriented in the same direction. The unit cell shown in Figure 15(a) can be characterized by the lattice parameters, $a = 0.9$ nm, $b = 1.1$ nm, and the angle of ca. 75\degree, indicating that the crystal violet adlayer was slightly deformed from threefold symmetry.

The third compound investigated is the highly symmetric cationic PPV molecule with two terminal pyridinium rings connected with the straight phenylenedivinylene core. The image shown in Figure 16 is a typical STM image of the ordered PPV adlayers formed on the I–Au(111) surface. The individual flat-lying PPV molecule can be
Figure 15 High-resolution STM image of crystal violet on I–Au(111). (Reprinted from M. Batina, M. Kunitake, K. Itaya, ‘Highly Ordered Molecular Arrays Formed on Iodine-modified Au(111) in Solution: In Situ Scanning Tunneling Microscopy Imaging’, J. Electroanal. Chem., 405, 245–250. Copyright (1996), with permission from Elsevier Science.)

seen as a linearly aligned feature consisting of three bright spots that can be attributed to the three aromatic rings in PPV. Three bright spots aligned in a straight line suggest that the PPV molecules adsorb on the I–Au(111) surface with a straight configuration. PPV molecules are expected to form straight or bent configurations, depending on the relative orientation of the two trans CH=CH double bonds. The STM image shown in Figure 16(a) indicates that the two trans CH=CH double bonds are located on opposite sides, forming the straight configuration in the adlayer shown in Figure 16. It is also clearly seen that the tightly packed arrangement forms long striped domains. In each domain, all molecules show the same orientation as indicated by the model in Figure 16(b). The width of each domain along the molecular axis was found to be ca. 2.1 nm from the STM image, which corresponds to the total molecular length of PPV. It is also interesting that a zig-zag arrangement appears alternately in these striped domains.

In this section, we have presented further evidence that the I–Au(111) electrode can be employed as an ideal substrate for in situ STM imaging of adsorbed organic molecules in solution. The organic substances investigated were all water-soluble cationic molecules with characteristic shapes: triangular, linear, and square. Molecules of crystal violet, PPV, and TMPyP were all
found to form highly ordered arrays on top of the iodine monolayer adsorbed on Au(111). The novel approach, using the iodine monolayer as an intermediate layer for the adsorption and formation of molecular arrays, has great potential for investigations of many organic molecules, including more complexed molecules and native biological materials.

In evaluating the structural relationship between iodine and TMPyP adlayers, we also investigated the structure of TMPyP on I–Pt(100). It was found that adsorbed TMPyP molecules formed a highly ordered adlayer with a side-by-side configuration. The adlayer structure of TMPyP on I–Pt(100) is controlled by the interaction between the iodine adlayer and TMPyP.\(^{(59)}\)

6 ADSORPTION OF AROMATIC MOLECULES ON CLEAN BARE ELECTRODES

The adsorption of organic molecules on bare electrode surfaces in electrolyte solutions under potential control has long been investigated for elucidating the role of the structures and properties of adsorbed molecules in EC reactions.\(^{(1,2,51)}\) Although conventional EC and optical techniques, such as infrared (IR), Raman, and second harmonic generation (SHG) spectroscopy, have been extensively applied to the investigation of the molecular adsorption at electrode surfaces in solution, they usually can provide only averaged information on the molecular orientation and packing within an adlayer. Ex situ techniques such as LEED and AES, using the UHVEC technique, have also been extensively employed for generating understanding of the relationship between the adsorbed molecules and the atomic structure of the electrode surfaces.\(^{(1,2)}\) More recently, in situ STM has been well recognized as an important in situ method for structural investigation of adsorbed chemical species on well-defined electrode surfaces in electrolyte solution with atomic resolution.

Although small inorganic species, such as halide, sulfate, cyanide, and thiocyanate, adsorbed on the metal electrode surface can be visualized relatively easily by in situ STM as described already, high-resolution STM images have rarely been reported for organic molecules adsorbed on bare metal surfaces.

In the previous section, it was demonstrated that highly ordered molecular arrays of porphyrine, crystal violet, and a linear aromatic molecule, PPV, were easily formed on iodine-modified Au(111) rather than on bare Au, and they were visualized in solution by in situ STM with near-atomic resolution, revealing packing arrangements and even internal molecular structures. Such an extraordinarily high resolution achieved in solution strongly encouraged us to investigate the adsorption of relatively small organic molecules such as benzene directly attached to the electrode surface in order to understand electrocatalytic activities of noble metals such as Pt and Rh.

On the other hand, many reports have describe the investigation of the adsorption in UHV of aromatics, such as benzene and its derivatives on Pt, Rh, Ni, Ir, Ru, and Pd, which were performed by using various surface-sensitive techniques such as LEED, AES, and electron energy-loss spectroscopy (EELS). The purpose of those investigations was to evaluate gas-phase catalytic
reactions, such as hydrogenation, dehydrogenation, and dehydrocyclization.\(^{(60)}\) In UHV the \((3 \times 3)\) superlattice of benzene and CO coadsorbed on Rh(111) revealed a well-ordered array of ring-like features associated with adsorbed benzene molecules, whereas CO did not appear in STM images.\(^{(61)}\) A more detailed STM study has been reported by Somorjai et al.\(^{(62)}\)

Nevertheless, we described, for the first time, the adlayer structures of benzene adsorbed on Rh(111) and Pt(111) in HF solutions.\(^{(63)}\) High-resolution STM images allowed us to determine the packing arrangement and even the internal structure of each benzene molecule in solution.

### 6.1 Benzene on Rhodium(111) in Hydrofluoric Acid

Figures 17(a) and (b) show CVs of Rh(111) and Pt(111) electrodes in the absence and presence of benzene in 0.01 M HF, respectively. In the absence of benzene, the CV obtained on the well-defined Rh(111) and Pt(111) exhibited several highly reversible characteristic peaks. It was noted that the heights and widths of these characteristic peaks depended on the quality of the surface of Rh(111) prepared by the flame-annealing and quenching method.

After the Rh(111) electrode had been subjected to the CV measurement in the pure HF solution, the electrode was transferred into 0.01 M HF solution containing ca. 1 mM benzene. The CV indicated a featureless double-layer region between 0.3 and 0.7 V, as shown in Figure 17(a). The cathodic current commencing at about 0.3 V was considered to be due to simultaneously occurring processes, such as the desorption of adsorbed benzene, the adsorption of hydrogen, and the irreversible hydrogenation of benzene to cyclohexane, according to previous studies using differential electrochemical mass

---

**Figure 17** CV of (a) Rh(111) and (b) Pt(111), (A) without and (B) with 1 mM benzene. (Reprinted with permission from S.-L. Yau, Y.-G. Kim, K. Itaya, ‘In Situ Scanning Tunneling Microscopy of Benzene Adsorbed on Rh(111) and Pt(111) in HF Solution’, *J. Am. Chem. Soc.*, **118**, 7795–7803.\(^{(63)}\) Copyright (1996), American Chemical Society.)
spectrometry (DEMS). A similar featureless CV was also obtained with a benzene-dosed Rh(111) electrode in pure 0.01 M HF. The Rh(111) electrode was immersed in 0.01 M HF containing 1 mM benzene for 1 min at the open-circuit potential (OCP) and then transferred to the pure HF solution. These results strongly suggest that benzene is chemisorbed and remains on the surface of Rh(111), at least in the potential range between 0.3 and 0.7 V.

A well-defined terrace-step structure was easily observed on the well-prepared Rh(111) face. The atomic image of Rh(111−1 × 1) was routinely discerned on the terrace in the pure HF solution. The almost perfectly aligned hexagonal structure can be seen with an interatomic distance of 0.27 nm, indicating that the structure of the Rh(111) surface is (1 × 1). Identical atomic images were consistently observed in the potential range between 0.1 and 0.75 V. No additional species were found in STM images at potentials corresponding to the butterfly peaks or the hydrogen adsorption and desorption peaks.

After achieving the atomic resolution, a small amount of 1 mM benzene solution was directly added to the STM cell at 0.45 V. The average concentration of benzene in 0.01 M HF was 10 µM. Immediately after the injection of benzene, completely different patterns appeared in STM images. Figure 18(a) shows an example of the STM images acquired at 0.45 V. It is evident that the atomically flat terraces are now covered by ordered benzene adlayers. An averaged domain size was about 10 × 10 nm. The adsorbed benzene molecules appear to form a square adlattice in each domain. Furthermore, the molecular rows in a given domain cross each other, forming boundaries at an angle of either 60° or 120°.

More details of the orientation of benzene in the adlayer are revealed by the higher-resolution STM image shown in Figure 18(b). The acquisition of the STM image was performed specifically under conditions with minimal thermal drift in the x and y directions in order to determine the unit cell of the adlayer as accurately as possible. It is seen in Figure 18(b) that the molecular rows along the direction of arrows A and B cross each other at 90°, and they are always parallel with the close-packed and √3 directions of the Rh(111) substrate, respectively. The intermolecular distances along these directions are not equal to each other and were found to be, on average, 0.8 and 0.9 nm, respectively. Based on the orientation of molecular rows and the intermolecular distances, we concluded that the benzene adlayer was composed of rectangular unit cells, namely c(2√3 × 3)rect (θ = 0.17), as shown in Figure 18(b). The known lattice spaces of 2√3 and 3 on Rh(111) (0.268 nm) correspond to 0.93 and 0.80 nm, respectively, which are consistent with our experimental values.

Surprisingly, the STM image allowed us to determine the internal structure and micro-orientation of each benzene molecule adsorbed on Rh(111). It is clear that each spot is split into two bright spots, forming a characteristic dumbbell shape for each benzene molecule. The STM discerned a 0.01 nm corrugation between the valley and ridge of each benzene molecule. It can also be seen in Figure 18(b) that the orientation of dumbbell-shaped benzene is not the same for all molecules, but depends on their positions. The dumbbell-shape of the central benzene molecule in the unit cell shown in Figure 18(b) is clearly rotated by 60° with respect to the molecules located on the four corners of the unit cell. The molecules on the corners of the unit cell...
appeared with an identical feature, suggesting that they are situated on an identical binding site. It is also seen that the orientation of these dumbbells is always rotated by 30° with respect to the direction of close-packed rows [arrow A in Figure 18(b)] of the Rh(111) substrate. The STM image shown in Figure 18(b) provides more detailed information on the orientation of molecule in the unit cell as discussed below.

The \( c(\sqrt{3} \times 3) \text{rect} \) structure described above was consistently observed in the potential range between 0.4 and 0.7 V without additional structural transitions. On the other hand, it was found that the adlayer structure changed at negative potentials. A negative potential step from 0.45 to 0.35 V induced a reconstruction in the benzene adlayer from \( c(\sqrt{3} \times 3) \text{rect} \) symmetry to an ordered hexagonal pattern. The electrode potential of 0.35 V is near the onset potential of the cathodic current as shown in Figure 17(a).

Figures 19(a) and (b) show a set of STM images acquired in almost the same area in order to reveal the dynamic process of phase transition. It is clearly seen in Figure 19(a) that a new domain appeared with the hexagonal array of benzene on the upper-right corner marked by solid lines, while the \( c(\sqrt{3} \times 3) \text{rect} \) structure remained as the main phase. A further cathodic step to 0.25 V resulted in a predominantly hexagonal phase, while eliminating the \( c(\sqrt{3} \times 3) \text{rect} \) domains as shown in Figure 19(b). Such a long-range ordered hexagonal pattern could be seen over almost the entire area of the terrace at 0.25 V. All benzene molecules exhibited the same corrugation height of 0.07 nm, similar to that in the \( c(\sqrt{3} \times 3) \text{rect} \) structure.

To reveal the internal molecular structure in the hexagonal phase, STM images were acquired under particularly carefully adjusted experimental conditions with minimal thermal drift. Figure 20(a) shows one of the highest resolution images acquired on the terrace shown in Figure 19(b). Compared with the crystal orientation, \([1]$N$10$\), determined by the Rh(111–1)$\,1$ atomic image, it can be seen that all benzene molecules are almost perfectly aligned along three close-packed directions of Rh(111). The molecular rows cross each other at an angle of either 60° or 120° within experimental error (±2°). The intermolecular distance along these rows was found to be 0.8 nm, which corresponds to three times the lattice parameter of Rh(111). Therefore, we conclude that the hexagonal structure is \((3 \times 3)\) benzene adlayer on Rh(111). The molecular rows cross each other at an angle of 60° or 120° within experimental error (±2°). The intermolecular distance along these rows was found to be 0.8 nm, which corresponds to three times the lattice parameter of Rh(111). Therefore, we conclude that the hexagonal structure is \((3 \times 3)\) benzene adlayer on Rh(111). The molecular rows cross each other at an angle of 60° or 120° within experimental error (±2°). The intermolecular distance along these rows was found to be 0.8 nm, which corresponds to three times the lattice parameter of Rh(111). Therefore, we conclude that the hexagonal structure is \((3 \times 3)\) benzene adlayer on Rh(111). The molecular rows cross each other at an angle of 60° or 120° within experimental error (±2°). The intermolecular distance along these rows was found to be 0.8 nm, which corresponds to three times the lattice parameter of Rh(111). Therefore, we conclude that the hexagonal structure is \((3 \times 3)\) benzene adlayer on Rh(111). The molecular rows cross each other at an angle of 60° or 120° within experimental error (±2°). The intermolecular distance along these rows was found to be 0.8 nm, which corresponds to three times the lattice parameter of Rh(111). Therefore, we conclude that the hexagonal structure is \((3 \times 3)\) benzene adlayer on Rh(111). The molecular rows cross each other at an angle of 60° or 120° within experimental error (±2°). The intermolecular distance along these rows was found to be 0.8 nm, which corresponds to three times the lattice parameter of Rh(111). Therefore, we conclude that the hexagonal structure is \((3 \times 3)\) benzene adlayer on Rh(111). The molecular rows cross each other at an angle of 60° or 120° within experimental error (±2°). The intermolecular distance along these rows was found to be 0.8 nm, which corresponds to three times the lattice parameter of Rh(111). Therefore, we conclude that the hexagonal structure is \((3 \times 3)\) benzene adlayer on Rh(111). The molecular rows cross each other at an angle of 60° or 120° within experimental error (±2°). The intermolecular distance along these rows was found to be 0.8 nm, which corresponds to three times the lattice parameter of Rh(111). Therefore, we conclude that the hexagonal structure is \((3 \times 3)\) benzene adlayer on Rh(111). The molecular rows cross each other at an angle of 60° or 120° within experimental error (±2°). The intermolecular distance along these rows was found to be 0.8 nm, which corresponds to three times the lattice parameter of Rh(111). Therefore, we conclude that the hexagonal structure is \((3 \times 3)\) benzene adlayer on Rh(111). The molecular rows cross each other at an angle of 60° or 120° within experimental error (±2°). The intermolecular distance along these rows was found to be 0.8 nm, which corresponds to three times the lattice parameter of Rh(111). Therefore, we conclude that the hexagonal structure is \((3 \times 3)\) benzene adlayer on Rh(111). The molecular rows cross each other at an angle of 60° or 120° within experimental error (±2°). The intermolecular distance along these rows was found to be 0.8 nm, which corresponds to three times the lattice parameter of Rh(111). Therefore, we conclude that the hexagonal structure is \((3 \times 3)\) benzene adlayer on Rh(111). The molecular rows cross each other at an angle of 60° or 120° within experimental error (±2°). The intermolecular distance along these rows was found to be 0.8 nm, which corresponds to three times the lattice parameter of Rh(111). Therefore, we conclude that the hexagonal structure is \((3 \times 3)\) benzene adlayer on Rh(111). The molecular rows cross each other at an angle of 60° or 120° within experimental error (±2°). The intermolecular distance along these rows was found to be 0.8 nm, which corresponds to three times the lattice parameter of Rh(111). Therefore, we conclude that the hexagonal structure is \((3 \times 3)\) benzene adlayer on Rh(111). The molecular rows cross each other at an angle of 60° or 120° within experimental error (±2°). The intermolecular distance along these rows was found to be 0.8 nm, which corresponds to three times the lattice parameter of Rh(111). Therefore, we conclude that the hexagonal structure is \((3 \times 3)\) benzene adlayer on Rh(111). The molecular rows cross each other at an angle of 60° or 120° within experimental error (±2°). The intermolecular distance along these rows was found to be 0.8 nm, which corresponds to three times the lattice parameter of Rh(111). Therefore, we conclude that the hexagonal structure is \((3 \times 3)\) benzene adlayer on Rh(111). The molecular rows cross each other at an angle of 60° or 120° within experimental error (±2°). The intermolecular distance along these rows was found to be 0.8 nm, which corresponds to three times the lattice parameter of Rh(111). Therefore, we conclude that the hexagonal structure is \((3 \times 3)\) benzene adlayer on Rh(111). The molecular rows cross each other at an angle of 60° or 120° within experimental error (±2°). The intermolecular distance along these rows was found to be 0.8 nm, which corresponds to three times the lattice parameter of Rh(111). Therefore, we conclude that the hexagonal structure is \((3 \times 3)\) benzene adlayer on Rh(111). The molecular rows cross each other at an angle of 60° or 120° within experimental error (±2°). The intermolecular distance along these rows was found to be 0.8 nm, which corresponds to three times the lattice parameter of Rh(111). Therefore, we conclude that the hexagonal structure is \((3 \times 3)\) benzene adlayer on Rh(111). The molecular rows cross each other at an angle of 60° or 120° within experimental error (±2°). The intermolecular distance along these rows was found to be 0.8 nm, which corresponds to three times the lattice parameter of Rh(111). Therefore, we conclude that the hexagonal structure is \((3 \times 3)\) benzene adlayer on Rh(111). The molecular rows cross each other at an angle of 60° or 120° within experimental error (±2°). The intermolecular distance along these rows was found to be 0.8 nm, which corresponds to three times the lattice parameter of Rh(111). Therefore, we conclude that the hexagonal structure is \((3 \times 3)\) benzene adlayer on Rh(111).

Figure 19 STM images of (a) domain boundaries of \( c(\sqrt{3} \times 3) \text{rect} \) and \((3 \times 3)\) benzene adlayers and (b) the pure \((3 \times 3)\) structure on Rh(111). Itaya, ‘In Situ Scanning Tunneling Microscopy of Benzene Adsorbed on Rh(111) and Pt(111) in HF Solution’, J. Am. Chem. Soc., 118, 7795–7803, Copyright (1996), American Chemical Society.)

islands with the same internal structure, suggesting that the desorption of benzene occurred preferentially at edges of the islands of ordered (3 x 3) domains. Eventually, all adsorbed benzene molecules were desorbed from the surface at 0.1 V owing partially to the hydrogen adsorption and partially to the hydrogenation as expected from the result obtained by DEMS, and the Rh(111-1 x 1) structure was consistently discerned at 0.1 V. The structural changes described above were reversible. When the electrode potential was stepped back to the positive region, the (3 x 3) and c(2\sqrt{3} x 3)rect phases returned at the potentials described above.

The structures and registries of chemisorbed benzene on Rh(111) have been thoroughly scrutinized by the surface-sensitive techniques, such as LEED, EELS, and angle-resolved ultraviolet photoemission spectroscopy (ARUPS), in UHV. These previous studies revealed various structures for benzene, including well-known structures such as c(2\sqrt{3} x 4)rect and (3 x 3), depending on whether CO was present unintentionally or intentionally in the UHV chambers. Although it has been repeatedly demonstrated that the adlayer structures of benzene on Rh and Pt were greatly affected by the presence of CO in the adlayer, the structure of the pure benzene adlayer is not yet fully understood. Neuber et al. have reported that a completely new structure with a (\sqrt{79} x \sqrt{19})R23.4° symmetry appeared for the pure benzene adsorption on Rh(111) under cleaner UHV conditions in the absence of CO, and the previously known structures of c(2\sqrt{3} x 4)rect and (3 x 3) were found to appear upon admission of CO.

However, it was found in our study that the anodic peak due to the oxidation of CO was hardly detectable in CV even after a prolonged STM experiment for several hours in an air-saturated HF solution. We strongly believe that the adlayer structures found in HF solution described above did not result from contamination with CO.

It is extremely important to recognize that in the previous study of the adsorbed benzene on Rh(111) in UHV, one of the structures of the pure benzene adlayer was attributed to the c(2\sqrt{3} x 3)rect structure, which was found in solution. This result strongly suggests that the existence of water molecule on top of the benzene adlayer plays a minor role in determining the structure of benzene.

Figure 21(a) shows a proposed model for the c(2\sqrt{3} x 3)rect structure. All of the adsorbed benzene molecules are assumed to be located on the twofold bridging sites. The benzene molecule at the center of the unit cell also occupies a twofold site, but it is rotated by 60° from the orientation of the molecules at the corners. Weiss and Eigler reported three distinct types of STM images for isolated benzene molecules located at threefold hollow, atop, and bridge sites on Pt(111) at 4 K. They assigned the single bump elongated perpendicularly to the bridge to the bridge-bonded benzene. In Figure 18(b) each benzene molecule is seen with the dumbbell shape on Rh(111) and elongated perpendicularly to the bridge. It is clear that the direction of each elongated dumbbell is always rotated by approximately 30° with respect to that of the corresponding atomic row of Rh(111).

These detailed features can be explained by the model structure shown in Figure 21(a), where two lobes marked...
The STM image obtained at 0.25 V shown in Figure 20 can be explained by the structural model with the \((3 \times 3)\) symmetry illustrated in Figure 21(b). Although the structure proposed here is basically the same as that proposed previously, based on LEED, EELS\(^{(60)}\) and STM\(^{(61)}\) studies in UHV, for the adlayer of coadsorbed benzene and CO on Rh(111), two CO molecules thought to be located at the threefold hollow sites in the unit cell are omitted in Figure 21(b). Each benzene molecule is assumed to bond at the threefold hollow site. The coadsorption of CO was unlikely to take place in the solution under the present conditions, because no oxidation peak was observed, as described above. Instead of CO, water molecules or hydronium cations might be coadsorbed near the uncoordinated threefold hollow sites to stabilize the \((3 \times 3)\) structure, their function being similar to that of the coadsorbed CO. The weak small spots seen in Figure 20 might be due to such coadsorbed water molecules or hydronium cations.

6.2 Other Molecules

The in situ STM imaging of benzene adlayers on Pt(111) was carried out in the same manner as that on Rh(111).\(^{(63)}\) It was found in our study that benzene adlayers on Pt(111) mostly appeared as less ordered phases than those on Rh(111). The intermolecular distances and directions of molecular rows indicate that the structure of the benzene adlayer at 0.35 V is \(c(2\sqrt{3} \times 3)\) _rect_ , the same as that found on Rh(111).

More interestingly, in situ STM revealed the reconstruction of the benzene adlayer that occurs upon the cathodic potential step from 0.35 to 0.25 V. On the basis of detailed results, we proposed that the benzene adlayer has a \((\sqrt{2}I \times \sqrt{2}I)R10.9°\) structure \((\theta = 0.14)\).\(^{(63)}\)

After the atomic resolution was achieved with Rh(111), a saturated naphthalene solution was added to the STM cell at 0.3 V.\(^{(67)}\) A high-resolution image acquired in an ordered domain is shown in Figures 22(a) and (b). It is clearly seen that the molecular rows parallel the \(h_{110}\) direction of the substrate indicated by the arrows in Figure 22(a). More importantly, the STM image allowed us to determine the internal structure and orientation of each naphthalene molecule. The elongated features along the longer molecular axis \((C_2)\) were discerned for each molecule. In addition, the images of some molecules clearly show a two-ring structure expected from the molecular model. It can be seen that naphthalene molecules are perfectly aligned with a regular micro-orientation along the molecular rows.

A typical arrangement of naphthalene molecules on Pt(111) was found to be a full monolayer of flat-lying naphthalene molecules. Although the overall appearance of the naphthalene adlayer on Pt(111) on the large
scale was similar to that on Rh(111), close inspection revealed that the adlayer included many randomly oriented molecules. Because the molecular rows were nearly parallel to the close-packed Pt atomic rows, and because the intermolecular distance was three times that of the Pt substrate, the structure roughly fitted a (3\(\times\)3) symmetry.

Periodic rotation of the molecules of naphthalene by 60° is seen within each molecular row with every third molecule being in the same orientation. A further magnified view in height-shaded mode is shown in Figure 22(b), in which the two-ring structure can be more clearly seen. The nearest-neighbor distance of 0.82 nm on average is equivalent to three times the Rh lattice parameter of 0.268 nm.

According to the results described above, the unit cell can be defined as a (3\(\sqrt{3}\times\)3\(\sqrt{3}\))R30° symmetry as shown in Figure 22(b).\(^{67}\) It is now clear that all naphthalene molecules align their \(C_2\) axes along the close-packed directions of Rh substrate. The molecules aligned along the (112) direction, which is the so-called \(\sqrt{3}\) direction, have the same orientation. The spacing between two adjacent molecules along the \(\sqrt{3}\) direction is measured to be 1.4 nm, which is three times the \(\sqrt{3}\) spacing. In our model structure,\(^{67}\) two carbon atoms at the 9- and 10-positions are assumed to be attached directly to a Rh atom. It is noteworthy that this structure is identical with that previously proposed from LEED results by UHV workers.\(^{68}\)

If one recalls the identical results for benzene adsorbed on Rh(111) in UHV and in HF solution as described above, the results obtained with naphthalene further support the predominant adsorbate–substrate interaction for hydrophobic molecules and the minor role of water molecules.

1,2- and 1,4-naphthoquinone can be considered as representative derivatives of naphthalene in order to understand the effect of functional groups on the molecular organization.\(^{67}\) Generally, these quinones, similarly to naphthalene, formed ordered adlayers on Rh(111) and mostly disordered adlayers with the flat-lying orientation on Pt(111). The high-resolution STM images revealed the details of internal molecular structures. It was demonstrated that 1,2-naphthoquinone formed a well-ordered adlayer with the structure (3\(\sqrt{3}\times\)3\(\sqrt{3}\))R30°, which was identical with that found for naphthalene. More interestingly, it was found that an additional bright spot, unseen in the image for naphthalene, is seen at the 2-position of each 1,2-naphthoquinone molecule.\(^{67}\) This spot exhibits a ca. 0.03 nm higher corrugation with respect to the naphthalene ring, which is likely to be due to the oxygen at the 2-position.

An STM image of anthracene on Rh(111) unambiguously disclosed the internal molecular structure of anthracene.\(^{67}\) It was also found that molecules of anthraquinone and 1,4,9,10-anthracenetetrol adsorbed in a manner similar to those of anthracene.

To elucidate the effect of molecular structure on the packing arrangement, biphenyl was further investigated on Rh(111).\(^{69}\) In contrast to the planar structure of naphthalene and anthracene, the two aromatic rings of biphenyl are slightly off the coplanar configuration because of the restriction of hydrogen atoms at the 2,2'- and 6,6'-positions. However, it was found that biphenyl formed disordered adlayers on Rh(111) in HF.\(^{69}\) Although STM images revealed the internal molecular structure of biphenyl with clear identification of
two rings in each molecule, the nonplanar configuration was not clearly seen. We expected that two rings of biphenyl behave like two benzene molecules, and they prefer to be attached on the bridge sites as benzene molecules do. The appearance of the disordered adlayer of biphenyl suggests that biphenyl is more strongly attached on Rh(111) than naphthalene.

It is of special interest to distinguish structures among a series of benzene derivatives such as phthalic acid, terephthalic acid, and hydroquinone.

7 ELECTROCHEMICAL DISSOLUTION PROCESSES OF SEMICONDUCTORS

The preparation of clean and stable semiconductor surfaces is the first step in the manufacture of semiconductor devices. The drive towards submicron technology for ultralarge-scale integrated circuits has focused special attention on wet chemical processes, since high-temperature-based procedures often lead to adverse effects that arise from new and difficult-to-control reaction channels; the pursuit of nanometer-scale technology has likewise necessitated the development of surface characterization methods that permit atomic-scale resolution. Since commercial integrated circuits are still based exclusively on silicon, the wet-chemical processing of Si single-crystal surfaces has been and continues to be widely investigated; much of the interest centers around the nature of the hydrogen termination of the Si surface atoms.

The first work to demonstrate that an Si(111) surface etched in aqueous NH₄F is ideally terminated with Si monohydride was based upon IR spectroscopic studies of the Si–H vibrational modes. This original work stimulated further investigations, likewise based upon IR and other spectroscopic techniques, on Si(100) and Si(110) substrates. STM in vacuum directly established the fact that the NH₄F-etched Si(111) surface was atomically well defined with an ideal H-terminated Si(111): H−(1 × 1) structure. While these studies provided critical information on the post-etched Si surfaces, it was clear that in situ investigations had to be undertaken if the chemical etching process is to be understood at the atomic level.

In response to this need, in situ STM and AFM were adopted for semiconductor-etching studies. Our first in situ STM observation of the Si(111): H−(1 × 1) atomic structure in a noncorrosive solution (aqueous H₂SO₄) spurred investigation of the etching of Si(111) in corrosive solutions, such as aqueous NH₄F and NaOH.

It was soon determined that the etching of Si(111) was potential dependent. At potentials markedly negative of the open-circuited potential (OCP), the etching rate decreased and the dissolution proceeded via a step-selective layer-by-layer mechanism. At potentials near or more positive than the OCP, the etching rate increased and pit corrosion occurred on the terraces, which resulted in atomically roughened surfaces. The potential dependence of the Si-etching process is a technologically relevant issue. Industrial wet-etching processes are usually performed without potential control, hence the surface chemical reactions that characterize the simple dipping of Si wafers in an etching bath are expected to bear a strong resemblance to what is observed from EC etching at the OCP. The ability to control the applied potential during the etching process may serve as an additional critical factor in the preparation of atomically well-defined semiconductor surfaces.

We have also demonstrated that in situ STM can be employed to monitor atomic-scale features of the etching process. For example, we discovered that, in general, multiple H-terminated Si atoms at the kink and step sites were eroded more rapidly than the monohydride-capped atoms. In this section, we first describe detailed etching processes of Si(111) in NH₄F solutions. Atomic images of GaAs and InP surfaces are also briefly discussed.

7.1 Silicon(111)

The STM imaging of the n-Si(111) electrode was performed immediately after the electrode was etched. After the Si electrode had been immersed in the NH₄F solution, the electrode potential of Si was immediately set to −1.1 V. Note that the potential effect on the etching rate of Si was reported in NaOH solutions. It was found that both chemical and EC etching mechanisms operate at the OCP, leading to a higher etching rate. We also found that applying a cathodic potential of −1.1 V drastically reduced the corrosion rate of Si in NH₄F solution.

Figures 23(a) and (b) show a crystallographic orientation and a ball-and-stick model, respectively, of an H-terminated Si(111) with [112] and [1T2] oriented steps. One of the most interesting features of an Si(111) surface is the existence of two structurally different steps where the Si atoms have monohydride and dihydride configurations. They can be exemplified by the steps in the [112] and [1T2] directions, respectively (Figure 23b). Ex situ STM results have shown that the dihydride-bound Si atoms are more reactive than those of the monohydride ones in weakly alkaline HF solutions, resulting in the appearance of the most stable [112] steps. Those experiments were conducted with Si(111) samples tilted towards [112] and [1T2]. Furthermore, there are two possible dihydride structures for the Si atoms at the [1T2] step. The dihydride axis is either perpendicular or parallel to the (111) plane.
It is believed that there is a strong repulsive interaction among the horizontal dihydride structures, so that the perpendicular dihydride, as depicted in Figure 23(b), is in fact more stable than the horizontal one, as confirmed by an IR spectroscopic study.\(^{(72)}\) The horizontal dihydride might be too reactive to exist on an Si(111) surface in the presence of etching species of \(\text{H}_2\text{O}\) and \(\text{F}^-\).

We focused our attention on the evaluation of the reactivity difference between the microscopically different steps on Si(111).\(^{(75)}\) We were able to use in situ STM to locate some areas which contain both types of steps so that the reactivity of these steps can be simultaneously examined under identical conditions. This approach is evidently more advantageous than that of the previous study which used differently tilted Si(111) substrates in separated experiments.\(^{(72)}\) As the initial surface feature of Si controlled the subsequent etching process, we first recorded an STM image at \(-1.1\ \text{V}\) to show the initial surface morphology as shown in Figure 24(a), followed by stepping the electrode potential to a less negative value of \(-1.04\ \text{V}\) to accelerate the erosion of Si. A series of STM images shown in Figures 24(b–f) was acquired successively with a time interval of \(13\ \text{s}\).\(^{(75)}\)

Figure 24(a) shows well-defined double-layer steps of 0.32 nm in height and terraces extending more than 25 nm on the (111) surface. The Si(111) was etched in 11 M \(\text{NH}_4\text{F}\) for 3 min at room temperature. The relative heights of terraces are reflected by their brightness in the STM image. The internal atomic structure of terrace (marked T) was readily discerned by a high-resolution STM scan. A well-ordered hexagonal pattern with an interatomic spacing of 0.38 nm was in good agreement with the ideal Si(111):H–1 \(\times \) \(\times \) 1 structure.\(^{(73)}\) Consequently, the treatment in 40% \(\text{NH}_4\text{F}\) yielded a long-range ordered monohydride-terminated Si(111) surface with no discernable vacancy defect in the hexagonal network. The step orientations, as defined by their outward normals, are shown in Figure 24(a). It is important to note that both the mono- and dihydride steps were probed by the in situ STM imaging at the same time. The shape of the terraces shown in Figure 24(a) was determined by the morphology of the step ledges, i.e. the monohydride steps are mostly straight, in strong contrast to the typical zig-zag pattern for the dihydride ones.

The small islands (3 nm in diameter, probably impurities) at the upper edge of the STM image were used as a guide against thermal drift during the STM measurement. Their unchanged locations indicate low thermal drift. The time-dependent STM results presented below demonstrate the important role played by the atomic structure at the steps in controlling the etching rate.

Figures 24(b–f) present the time-dependent etching process of Si(111) after acquiring the image of Figure 24(a). During the first 13 s etching of the Si from Figures 24(a) to (b), the width of the upper portion of the terrace T marked by D decreased from 16 to 8 nm, while the lower portion marked by D' retracted from 18 to 12.5 nm. The relatively faster erosion of the upper half of the [1\(\overline{1}\)2] dihydride step is thought to be due to the higher kink density within the zig-zag pattern step ledge. On the other hand, the monohydride step in the direction of [1\(\overline{1}\)2] seems to be unchanged from Figures 24(a) to (b). In particular, the steps within the circle marked C in Figure 24(b) remained still in both images, indicating that the ideal monohydride [1\(\overline{1}\)2] and [\(\overline{1}\)1\(\overline{1}\)] step in the absence of kink sites is inactive under
Figure 24 Successively recorded STM images for the etching process of Si(111) in NH₄F. The images were acquired at time intervals of 12.8 s. (Reprinted with permission from K. Kaji, S.-L. Yau, K. Itaya, ‘Atomic Scale Etching Processes of n-Si(111) in NH₄F Solutions: In Situ Scanning Tunneling Microscopy’, *J. Appl. Phys.*, 78, 5727–5733, (1995).)
the present etching conditions. The dihydride-terminated steps continued to retract rapidly to dissolve the terrace T, leaving a small isolated island I in Figure 24(c). However, it was surprising to find that the [TT2] step with the dihydride configuration marked by D’ in Figure 24(c) was essentially unchanged from Figures 24(b) to (c). The well-defined step ledge, marked D’ in Figure 24(c), suggests that an ideal dihydride step without kinks is also stable.

After the complete removal of the island I in Figure 24(c), a small, bilayer deep (0.32 nm) pit evolved in Figure 24(d). This newly formed depression is apparently a real pit, not an imaging artifact, because it expanded and coalesced with an adjacent [112] step, as shown in Figure 24(e). This coalescence introduced many kink sites (marked K) in Figure 24(e) at the almost inactive [112] step. A close examination of Figures 24(e) and (f) reveals the very important fact that the etching rate of the [112] monohydride step is now increased by the introduction of the kinks into the nearly ideal monohydride step. The [112] step line retracted by ca. 3 nm within 13 s, which corresponds to an etching rate of 14 nm min⁻¹. This is a significant increase from a negligible level for the ideal monohydride step as observed in Figures 24(a) and (b).

The aforementioned results provide compelling evidence that the difference in the chemical reactivity of the monohydrogen-terminated and dihydrogen-capped Si surface atoms profoundly influences the Si-etching process. We extended our investigations of the EC etching of Si(110) and Si(100).\(^{74,76}\)

### 7.2 Other Semiconductors

It is becoming more urgent for workers in semiconductor technology to understand wet-chemical etching processes, particularly those of Si, GaAs, and InP with atomic resolution.

We acquired the first atomic STM images of GaAs surfaces in 0.05 M H\(_2\)SO\(_4\) solution.\(^{81–83}\) The results clearly demonstrate that the ideal GaAs(001–1 × 1) and (111–1 × 1) structures exist in a pure H\(_2\)SO\(_4\) solution in a cathodic potential region. The samples were n-type Si-doped GaAs(001), (111)A and (111)B wafers, grown by the horizontal Bridgman method. The GaAs(001) and (111)B samples were treated in 1 M HCl for 10 min at room temperature. The GaAs(111)A sample was etched with an etching solution [H\(_2\)SO\(_4\)–H\(_2\)O\(_2\)–H\(_2\)O (1 : 8 : 1 by volume)]. The etching rate of the (111)A surface has been reported to be the lowest among all low-index planes in this mixed solution. After the etching, the solution was completely replaced with 0.05 M H\(_2\)SO\(_4\). The replacement of the etching solution was carried out repeatedly to exclude HCl in the solution. It is important that the GaAs surface should always be kept submerged in the solution in order to protect it from oxidation and contamination in the ambient atmosphere.

Figure 25(a) shows a typical surface topography of a chemically etched GaAs(001) surface acquired in an area of 50 × 50 nm. It can be clearly seen that the surface of the (001) exhibits a well-defined step-terrace structure extending over a large area. Wider terraces are seen to extend over 30 nm. The relative brightness of the terraces in the STM image reflects their heights on the surface, i.e. the surface ascends from left to right. The rather uniform appearance of the terraces strongly suggests that the (001) surface has a structure that is well defined on an atomic scale. It is also clear that the steps intersect each other to form an angle of 90°, as expected for a surface with fourfold symmetry. These steps appearing as straight lines were confirmed as double-layer steps on the (001) surface based on the observed height of 0.28 nm obtained by a cross-section analysis. This unique height of 0.28 nm for the steps indicates straightforwardly that the (001) surface prepared by etching in HCl must be either Ga- or As-terminated. According to the crystallographic orientation of the GaAs(001) electrode, these steps were found to be parallel to either [110] or [\(\overline{110}\)] directions.

Figure 25(b) shows our first atomic STM image of an atomically flat terrace on a GaAs(001) surface. It is clear that the ideal square arrangement expected for the (001) surface with fourfold symmetry is discerned by in situ STM. The observed nearest interatomic distances in the [110] and [\(\overline{110}\)] directions were found to be 0.4 ± 0.02 nm. The atomic image shown in Figure 25(b) clearly demonstrates that the ideal, nonreconstructed GaAs(001–1 × 1) structure is exposed in H\(_2\)SO\(_4\) solution under the cathodic polarization. Note that the ideal (1 × 1) structure seemed to be extended over the entire region of the terrace, because pits or even single atomic defects were rarely observed.

The (111)A surface etched in the mixed solution containing H\(_2\)O\(_2\) was also found to have an atomically flat terrace-step structure in H\(_2\)SO\(_4\) solution as shown in Figure 26(a). All steps observed were double-layer steps with a height of 0.33 nm. The steps in local areas were straight and parallel to the close-packed atomic row direction of (111) surface. Figure 26(b) shows a typical atomic STM image, revealing an interatomic distance of 0.4 nm with an almost perfect hexagonal arrangement. This result clearly demonstrates that the ideal GaAs(111)A–(1 × 1) structure, as shown in Figure 27(c), is exposed in H\(_2\)SO\(_4\) solution. It is reasonably expected that the uppermost layer on the (111)A surface consists of Ga atoms.

Finally, it is noteworthy that the GaAs(111)B surface prepared by etching in 1 M HCl also showed an atomically flat terrace-step structure in H\(_2\)SO\(_4\) with a step height identical with that observed on the (111)A
surface. Although the average terrace width was typically 5–10 nm, obviously smaller than that found on the A surface, an atomic STM image revealed a hexagonal arrangement of As atoms with an interatomic distance of 0.4 nm. The above results indicate that the GaAs(111)B surface has also the ideal (1 × 1) structure shown in Figure 27(d).

In summary, it was demonstrated that the well-defined GaAs(001), (111)A, and (111)B surfaces can be prepared by chemical etching in solutions. Atomically flat terrace-step structures were consistently observed by in situ STM on all three surfaces in H₂SO₄ solution under potential control. Furthermore, we successfully obtained the first atomic STM images which showed that the ideal GaAs(001–1 × 1), GaAs(111)A–(1 × 1), and GaAs(111)B–(1 × 1) structures are exposed and persist in H₂SO₄ solution.

In spite of the fact that InP is a very important material for both optoelectronic and electronic device applications,
there have been a fewer STM studies on InP than on GaAs. Previous STM studies of InP were mostly carried out in UHV.

We have recently shown the first atomically resolved STM images of InP(001), (111)A, and (111)B surfaces in an H_2SO_4 solution under cathodic potential control, which effectively protected the surfaces from oxidation. These images clearly demonstrate that well-defined InP surfaces can be prepared by chemical etching in HCl solution. In STM images, individual atoms were relatively clearly observed on the atomically flat terraces of the (111) surface with a corrugation height of ca. 0.02 nm. Monolayer steps were found to be exactly parallel to the close-packed atomic row direction of the (111) surface. An atomically resolved STM image of the (111)A surface revealed a perfect hexagonal arrangement of In atoms with an interatomic distance of 0.42 nm, as expected for the ideal InP (111)A surface. These results clearly demonstrate that the ideal InP(111)A–(1×1) structure is exposed in the H_2SO_4 solution after the chemical etching. This (1×1) structure seemed to extend over the entire region of the terrace; even atomic defects were rarely observed.

On the other hand, the chemically etched (111)B surface also possessed a well-defined structure in H_2SO_4 solution. An atomically flat terrace-step structure was observed with a step height identical with that on the A surface, although the average terrace width was typically 5–10 nm, which was smaller than that on the A surface. The appearance of wider terraces on the (111)A surface is reasonable, because the etching rate of (111)A surface in HCl solution is the slowest of all low-index planes.

An almost ideal square arrangement expected for the (001) surface was clearly discerned by in situ
STM. The observed interatomic distances in the [110] and [110] directions were found to be equal to 0.42 nm. Atomic images clearly demonstrate that the ideal InP(001–1×1) structure exists in H₂SO₄ solution under cathodic potential control. We also presume the InP(001–1×1), (111)A–(1×1) and (111)B–(1×1) surfaces to be terminated by hydrogen, at least under cathodic polarization.

In summary, it has been demonstrated that well-defined InP(001), (111)A, and (111)B surfaces can be prepared by chemical etching in HCl solution. In situ STM revealed atomically flat terrace-step structures on each surface in H₂SO₄ solution under proper potential control. Furthermore, we successfully obtained the first atomic resolution STM images of InP surfaces, which showed that the ideal InP(001–1×1), (111)A–(1×1) and (111)B–(1×1) structures are exposed and persist in H₂SO₄ solution under EC conditions.

8 CONCLUSION

The methods for exposing well-defined electrode surfaces in solution were reviewed. The flame-annealing and quenching method can be applied to Au, Pt, Rh, Pd, and Ir single-crystal electrodes. The UHVEC method can be used for Pt, Au, Pd and Rh. For some metals, such as Ni and Cu, surface oxidation takes place in the EC chamber before immersion of the electrode in electrolyte solutions. It was demonstrated that the EC etching method produced atomically flat terrace-step structures of semiconductors under carefully adjusted EC conditions. The method of anodic dissolution is expected to become an important in situ technique for exposing well-defined surfaces of various semiconductors and metals. The structures of specifically adsorbed iodine on Pt(111) and Au(111) and briefly on Ag(111) were discussed, demonstrating that complementary use of in situ STM and ex situ LEED is a powerful combination to characterize the atomic structure of adsorbed iodine. The adsorption of sulfate/hydrogensulfate adsorbed on Au(111), Pt(111), and Rh(111) was described, with emphasis on the fact that the same (√3×√3) structure is formed on these three substrates. Our model indicates that hydrogen-bonded water chains are inserted along the √3 direction between neighboring rows of the adsorbed sulfates. The detailed structural analysis of the CN adlayer on Pt(111) was carried out by in situ STM, revealing that six CN groups form a hexagonal ring without an additional CN at the center of the ring. The complexation of K⁺ with the CN adlayer was also discussed.

The UPD of Cu on Au(111) in H₂SO₄ was discussed in depth. In situ SXS indicated that the Cu atoms form a honeycomb lattice and are adsorbed on threefold hollow sites with sulfate ions located at the honeycomb centers. According to the model structure, the corrugation observed by in situ STM and AFM should be ascribed to the coadsorbed sulfate ions, and not the Cu atoms.

It was shown that, in general, the iodine-modified electrodes are suitable for producing highly ordered adlayers of various organic molecules. TMPyP forms highly ordered adlayers on I–Au(111), I–Ag(111), and I–Pt(100).

The adlayer structure of benzene on Rh(111) and Pt(111) was also described in detail; it was found to be dependent on the electrode potential. The (3×3) structure found on Rh(111) in the cathodic potential range is almost identical with that found in UHV for the coadsorbed benzene and CO. The molecular shapes of naphthalene and anthracene could be clearly discerned by in situ STM.

The EC etching processes of Si(111), Si(110), and Si(100) were discussed in relation to the atomic structures of the step-edges. It was shown that the chemical etching produces well-defined GaAs and InP single-crystal electrodes. The atomic structures of these electrodes in solution could be clearly seen.

This article clearly demonstrates that STM allows us not only to determine interfacial structures but also to follow EC reactions. It is certain that in situ STM will continue to be the premier technique in the study of the relationship between the reactivity and the structure of electrode surfaces.

Selective Electrode Coatings for Electroanalysis

Lee J. Klein and Dennis G. Peters
Indiana University, Bloomington, USA

1 INTRODUCTION

In the realm of electroanalysis, one of the greatest challenges is to design and fabricate an electrode that ideally will respond both selectively and sensitively to a particular chemical species (e.g. a simple inorganic cation or anion, a metal–ion complex, or an organic or biological material). Over the past 30 years or so, tremendous advances have been made in our ability to tailor or modify chemically the surfaces of electrodes to enhance their selectivity and sensitivity for a variety of analyses. In a sense, these advances constitute a form of molecular engineering, in which one knowledgeably and purposefully redesigns or alters the surface of an electrode to try to define and control how that electrode responds to one targeted species or to a family of species. In this short article, we attempt to introduce and describe some of these advances.

Four different categories of selective electrode coatings have been chosen for discussion. First, we begin with SAMs on electrodes; a SAM is an organized array of molecules strongly adsorbed or chemically bonded to an electrode surface, and such a monolayer can form spontaneously when a carefully prepared electrode surface is brought into contact with an appropriate species that can interact with the surface. Second, we consider polymer-coated electrodes; most simply, one can create a polymer-coated electrode (a) by electropolymerizing a selected (and perhaps functionalized) monomer directly onto the surface of an electrode or (b) by coating or depositing a preformed (and functionalized) polymer onto an electrode surface. Third, we describe the preparation of Langmuir–Blodgett films on electrodes; a Langmuir–Blodgett film is an ordered monolayer of amphiphilic molecules formed at a liquid/gas interface, and this film is subsequently transferred mechanically to the surface of an electrode. Fourth, we discuss the immobilization of enzymes onto electrodes, which can be accomplished in a variety of ways, including electrostatic self-adsorption and incorporation into SAMs, polymer films, or Langmuir–Blodgett films.

Recent progress in this area of research and development has been so great that we have been forced to be selective in choosing the topics, examples, and references included in this article. Thus, we can offer only a brief glimpse into this highly interesting subject. Obviously, by referring to the cited reviews and original papers, and by seeking out other publications by the major contributors to this field, the interested reader can find more information.

2 SELF-ASSEMBLED MONOLAYERS ON ELECTRODES

When an electrode (substrate) is immersed into a solvent in which an appropriate surfactant is dissolved, the molecules of surfactant can interact (react) spontaneously...
at the surface of the electrode to give a SAM. From the viewpoint of electroanalysis, an excellent example of such a self-assembly process is seen in the spontaneous formation of a SAM consisting of a functionalized alkanethiol on the surface of a gold electrode. For purposes of illustration, let us assume that we have a solution of (C\textsubscript{5}H\textsubscript{5})Fe(C\textsubscript{5}H\textsubscript{4})CONH(CH\textsubscript{2})\textsubscript{6}SH in ethanol. Typical of many surfactants, (C\textsubscript{5}H\textsubscript{5})Fe(C\textsubscript{5}H\textsubscript{4})CONH(CH\textsubscript{2})\textsubscript{6}SH consists of three moieties: (a) the surface-active head group, –SH, which tethers the molecule to the gold surface via the formation of an S–Au bond; (b) the alkyl group, –(CH\textsubscript{2})\textsubscript{n}–, which is essentially a spacer that separates the head group from the end group; and (c) the end group itself, (C\textsubscript{5}H\textsubscript{5})Fe(C\textsubscript{5}H\textsubscript{4})CONH–, which is farthest from the surface of the gold electrode and which imparts desirable characteristics to the SAM on gold (such as selectivity toward a particular species in a solution to be analyzed). Figure 1 depicts the spontaneous process by which this functionalized alkanethiol, originally dissolved in ethanol, forms a SAM on gold.

Although details of the mechanism of adsorption of an alkanethiol are still unclear, the most important step in the formation of a SAM on gold is chemisorption of the deprotonated (thiolate) form, (C\textsubscript{5}H\textsubscript{5})Fe(C\textsubscript{5}H\textsubscript{4})CONH(CH\textsubscript{2})\textsubscript{6}S\textsuperscript{−}, onto the gold surface.\(^2\) Then, as more and more of the thiolate form becomes attached (adsorbed) to the gold surface, the assembly of a closely packed (ordered) SAM takes place.

### 2.1 Types of Materials Used

Since the pioneering work of Zisman,\(^4\) who investigated the wetting behavior of solutions of surfactants, several classes of compounds have been used to prepare SAMs. First, long-chain carboxylic (n-alkanoic) acids can be adsorbed onto a variety of substrates, including aluminum oxide,\(^5\) silver,\(^6\) and iron oxide.\(^7\) In addition, diacetylenic carboxylic acids, such as CH\textsubscript{3}CH(C\textsubscript{5}H\textsubscript{11})=C=CHC(CH\textsubscript{3})\textsubscript{6}COOH, have been used to prepare SAMs on glass, quartz, and silicon;\(^8\) although such substrates cannot serve as electrodes, they could be rendered conductive by being coated with thin layers of indium-doped tin oxide (ITO) prior to the formation of the SAM. Second, alkylsilane derivatives can be bonded onto hydroxylated surfaces; for example, compounds such as RSiX\textsubscript{3}, R\textsubscript{2}SiX\textsubscript{2}, and R\textsubscript{3}SiX (where R is an alkyl chain, which may or may not be functionalized with a suitable electroactive end group, and X is a chloro or alkoxy moiety) can be attached to glass,\(^9\) silicon dioxide,\(^10\) or aluminum oxide,\(^11\) via the formation of stable Si–O bonds. Once again, the strategy of coating the substrate with a thin layer of ITO (which is also a hydroxylated surface) can provide a conductive electrode onto which the SAM can form. When a trichlorosilane (RSiCl\textsubscript{3}) is used to prepare a SAM on one of these hydroxylated substrates, it is possible to obtain a cross-linked network, as illustrated in Figure 2.

Third, as described earlier, functionalized organosulfur compounds such as alkanethiols, dialkyl sulfides, and dialkyl disulfides can form SAMs on gold,\(^12\) copper,\(^13\) nickel,\(^14\) mercury,\(^15\) and platinum\(^16\) surfaces. Gold is much preferred, however, because it has the least tendency to form a surface oxide and is, therefore, the easiest substrate to prepare and handle.

### 2.2 Methods of Preparation

Many of the articles cited in the preceding section contain specific procedures employed to prepare SAMs; the reader is encouraged to consult these sources. However, for illustrative purposes, it is useful to examine some key steps of a general protocol for the formation of a SAM consisting of a functionalized alkanethiol on gold. First, the particular gold substrate must be selected; one may use either a polycrystalline (rough) gold surface or an evaporated (smooth) gold surface. Second, the gold surface is usually cleaned (freed of adventitious impurities) by being heated, immersed in solutions of strong oxidants, exposed to an argon or...
SELECTIVE ELECTRODE COATINGS FOR ELECTROANALYSIS

3

oxygen plasma, or placed in a suitable electrolytic cell whereupon the potential of the gold electrode is cycled; often a combination of these techniques is used. Third, the desired functionalized alkanethiol (which must often be synthesized) is dissolved in an appropriate organic solvent; typically, the concentration of the alkanethiol is \(10^{-3}\) M. Fourth, the gold substrate is immersed into the alkanethiol solution for times ranging from minutes to 12 h or longer at room temperature to promote the self-assembly process. Finally, after being rinsed, the monolayer-covered gold electrode may be annealed thermally to cause the monolayer to rearrange into a more ordered structure.

2.3 Methods of Characterization

Several electroanalytical techniques can be used to study and characterize SAMs on electrodes. Cyclic voltammetry is the most popular method, but differential pulse voltammetry, chronoamperometry, and hydrodynamic voltammetry deserve mention.

Ulman and Finklea have reviewed the literature on the various nonelectrochemical techniques that can be employed to characterize SAMs. Although space limitations prevent any detailed discussion of these methods, it is useful at least to list some of these techniques, most of which are completely described elsewhere in this encyclopedia. Many workers have utilized wetting contact angle to elucidate the structure of SAMs. Both infrared and Raman spectroscopy as well as ellipsometry and surface plasmon resonance techniques have been used. High-vacuum surface methods such as X-ray photoelectron spectroscopy (XPS), Auger electron spectroscopy (AES), high-resolution electron energy loss spectroscopy (HREELS), and low-energy electron diffraction spectroscopy (LEEDS) have been employed. Scanning tunneling microscopy (STM) and atomic force microscopy (AFM) can provide images of alkanethiol-based SAMs on gold substrates. Some investigators have used the electrochemical quartz crystal microbalance (EQCM) to probe the kinetics of self-assembly of alkanethiols onto gold surfaces.

2.4 Analytical Applications

Despite enormous interest in the preparation and properties of SAMs, especially those involving functionalized alkanethiols on gold electrodes, the list of practical analytical applications is still somewhat limited. A review by Mandler and Turyan summarizes the literature through mid-1995 on the use of SAMs in electroanalytical chemistry. Citing a few examples of analytical applications will help to convey the excitement and promise of this area of research.

Steinberg and Rubinstein found that a mixed SAM, composed of 2,2’-thiobisethyl acetoacate and \(n\)-octadecyl mercaptan, on a gold substrate can be used to determine Cu\(^{2+}\) in the presence of Fe\(^{3+}\), and that replacing \(n\)-octadecyl mercaptan with \(n\)-octadecyltrichlorosilane afforded an electrode system for the detection of trace levels of Cu\(^{2+}\) (\(10^{-7}\) M), Pb\(^{2+}\) (\(10^{-5}\) M), and Zn\(^{2+}\) (\(10^{-9}\) M). A novel microsensor for pH measurements has been developed that is based on the coadsorption of ferrocenyl and quinone thiols onto a gold microelectrode; the redox potential for the ferrocenyl moiety is independent of pH, but the redox potential for the quinone moiety is pH dependent, so the difference in these redox potentials is related to the pH of the sample.

Turyan and Mandler have devised a highly sensitive and selective method for the determination of Cd\(^{2+}\); a detection limit as low as \(4 \times 10^{-12}\) M was obtained. These workers prepared SAMs, consisting of \(\omega\)-mercaptopcarboxylic acids (HS(CH\(_2\))\(_n\)COOH, where \(n = 2, 3, 6, \) and 11) adsorbed onto both thin mercury film and gold electrodes. When placed into a buffered solution containing Cd\(^{2+}\), the modified electrode acts to preconcentrate Cd\(^{2+}\), possibly through formation of a complex involving the interaction of Cd\(^{2+}\) with both the sulfur and carboxylate moieties of the SAM. After the preconcentration step, the complexed cadmium(II) can be determined by means of voltammetry.

Another approach for gaining selectivity for electroanalysis involves the incorporation of so-called “molecular gates” in an otherwise blocking monolayer. Two mercaptans, 1-hexadecanethiol and 4-hydroxythiophenol, are coadsorbed onto a gold surface to form the SAM; the first compound is a passivating (blocking) substance, whereas the second species acts as an electron-transfer site (the “molecular gate”). These “molecular gates” allow [Ru(NH\(_3\))\(_6\)]**+, but not [Fe(CN)\(_6\)]**-, to undergo a reversible one-electron reduction.

Chlorpromazine in human urine has been measured by means of an amperometric flow detector coated with unsubstituted \(n\)-alkanethiols on gold.

By varying the chain length of the alkanethiol, one can tailor the permselective properties of the SAM so that other constituents of the urine are prevented from reaching the gold surface. In the same study, it was shown that such a SAM-coated detector can distinguish dopamine (a neurotransmitter) from ascorbate; this approach overcomes the difficult problem of detecting dopamine in cerebral fluid, which contains relatively high concentrations of ascorbate.

A method to determine glucose relies on the mediated oxidation of the reduced form of glucose oxidase (GOx(red)), by dicationic (ferricenylmethyl)dimethylacetacly ammonium ion (C\(_{18}\)Fe\(^{2+}\)), which is incorporated into a self-assembled bilayer.
Preparation of the bilayer begins with the spontaneous reaction of octadecyltrichlorosilane with a film of microporous aluminum oxide to form a cross-linked SAM. After gold is evaporated onto the back of the SAM–Al2O3 assembly, (ferrocenylmethyl)dimethyloctadecyl ammonium ion (C18Fc+) is allowed to interleave with the silanized surface to form a bilayer, and glucose oxidase (GOx) is immobilized on the bilayer. In the presence of glucose, the following reactions (Equations 1–3) occur

\[ \text{GOx} + \text{glucose} \rightarrow \text{GOx}(\text{red}) + \text{gluconolactone} \quad (1) \]
\[ \text{GOx}(\text{red}) + 2\text{C18Fc}^2+ \rightarrow \text{GOx} + 2\text{C18Fc}^+ + 2\text{H}^+ \quad (2) \]
\[ \text{C18Fc}^+ + \text{e}^{-} \rightarrow \text{C18Fc}^2+ \quad (3) \]

where the last process gives rise to a steady-state voltammetric current that is related to the original concentration of glucose.

3 POLYMER-COATED ELECTRODES

Although electrodes coated with a variety of polymer films have been prepared, there are essentially three major types of polymers to consider here: electronically conducting organic polymers, polymers containing electroactive metal-ion sites, and ion-exchange polymers.

3.1 Organic Conducting Polymers

3.1.1 Types of Materials Used

Two of the best examples of organic conducting polymers are polypyrrole (1) and polythiophene (2). Other conducting polymers include polyacetylene, polyaniline, poly-p-phenylene, polyazulene, polyindole, and polyfuran. Moreover, it is possible to prepare copolymers consisting of two different monomers (such as a mixture of thiophene and pyrrole\(^{(33,34)}\)), and even more exotic starting materials (such as 1-thienyl-2-cyano-2-phenylethylene\(^{(35,36)}\)) can be used. Information about the properties of conducting polymers on electrodes can be found in two reviews\(^{(37,38)}\)

\text{H}
\end{array}
\quad \quad
\begin{array}{c}
\text{S} \\
\text{H}
\end{array}
\]

(1) (2)

3.1.2 Methods of Preparation

There are several important requirements for the successful electrochemical preparation of a polymer film on an electrode: the parent monomer must be readily oxidizable (reducible) at an electrode in the chosen solvent–electrolyte; the radical cation (anion) arising from oxidation (reduction) of the monomer must react rapidly with other monomeric species to grow the polymer; the polymer must have a relatively low solubility so that it will deposit on the electrode; and the polymer must have an oxidation (reduction) potential less (more) positive than that of the monomer if the polymer is to have a high conductivity. A common procedure\(^{(39)}\) for the formation of a film of polypyrrole on a platinum substrate involves the controlled-potential electrolysis of a solution of 50 mM pyrrole in acetonitrile containing 0.10 M tetraethylammonium tetrafluoroborate. Films are grown slowly by proper choice of the potential, the thickness of a film (typically 20–80 nm) is controlled by the amount of charge passed, and oxygen is excluded from the system. Polypyrrole films can also be prepared by means of constant-current electrolysis, and polypyrrole can be deposited onto other substrates including carbon, gold, palladium, and ITO.

Electrochemical techniques for the preparation of some of the other polymeric films mentioned above are similar to those used to obtain polypyrrole coatings. In addition, one can prepare some conducting polymers by casting a soluble precursor polymer onto a chosen substrate and by heating the system to form the desired material.\(^{(37)}\) Alternatively, if the conducting polymer can be synthesized by a convenient chemical procedure and if the polymer is soluble in a volatile solvent, a solution of the polymer can be applied to an electrode surface by means of dip- or spin-coating, and the solvent can be evaporated to produce the polymer-coated electrode.

3.1.3 Methods of Characterization

Most of the methods mentioned in section 2.3 can be utilized to characterize polymer films on electrodes. Scanning electron microscopy (SEM) and transmission electron microscopy (TEM) are other useful approaches. A rich source of both electrochemical and nonelectrochemical techniques for the study of conducting polymers is a review by Dobhalhofer and Rajeshwar.\(^{(40)}\)

One of the most important properties of a conducting polymer film is its conductivity, which can be measured by means of the classic four-probe method.\(^{(41)}\) Conductivity of a conjugated polymer film arises from partial oxidation (p-doping) or partial reduction (n-doping). In electrochemical p-doping – which all of the polymers mentioned so far undergo – electrons are withdrawn from the polymer, and the polymer becomes positively charged. Then anions (usually from the supporting electrolyte) diffuse into the polymer to provide charge compensation; thus, the choice of supporting electrolyte can affect the nature of the conducting polymer. In combination, all of these processes profoundly influence the formation, structure,
and conductivity of organic polymers; these issues are discussed in two previously cited reviews.\(^{37,38}\)

### 3.1.4 Analytical Applications

Several kinds of analytical applications have been developed that involve the use of an electrode coated with a film of conducting organic polymer. Examples in the present section have been chosen to exclude situations where the polymer film also contains either trapped transition-metal sites (see section 3.2) or an immobilized enzyme (see section 5).

Shiu et al.\(^{42}\) have reported that, when pyrrole is oxidatively polymerized onto a glassy carbon electrode in the presence of either bathophenanthroline disulfonate or bathocuproine disulfonate, these electroinactive anionic complexing agents are incorporated into the polymer. When Cu\(^+\) or Cu\(^{2+}\) is extracted (via formation of a complex) from a sample solution into the polymer, a cyclic voltammetric peak current is seen that can be used to determine these cations; the electrode responds better to Cu\(^+\) than to Cu\(^{2+}\), and the detection limit for Cu\(^+\) is approximately \(2 \times 10^{-6}\) M. In their paper, the authors review earlier efforts to develop polymer-coated electrodes for the determination of other metal cations.

Because p-doping of a polymer is associated with incorporation of anions, this phenomenon can be utilized to fabricate polymer-coated electrodes that respond to anions in a sample solution. This principle has been employed for the development of a polypyrrole-coated platinum electrode for the flow injection analysis (FIA) of phosphate, carbonate, and acetate;\(^{43}\) the electrode response to phosphate and carbonate is linear over the concentration range from \(10^{-5}\) to \(10^{-3}\) M. Similarly, a polyaniline-coated glassy carbon electrode for the FIA of iodide, bromide, thiocyanate, and thiosulfate has been devised, with detection limits of 1, 5, 10, and 10 mg L\(^{-1}\), respectively.\(^{44}\) A poly(3-methylthiophene)-coated graphite electrode has been constructed for the potentiometric determination of iodide, chloride, bromide, and sulfite;\(^{45}\) for the measurement of iodide, the linear dynamic range of the electrode is \(1 \times 10^{-7}\) to \(5 \times 10^{-3}\) M, and the detection limit for iodide is \(1 \times 10^{-8}\) M.

A platinum electrode coated with polypyrrole with incorporated anti-human serum albumin (serving as a charge-compensating anion) has been found to respond linearly in alternating current (AC) voltammetric experiments to human serum albumin at concentrations ranging from 10 to 50 \(\mu\)g mL\(^{-1}\).\(^{46}\) Polypyrrole on glassy carbon, as well as polypyrrole on mercury-filmed glassy carbon, provides a sensor for the amperometric determination of dichloramine separated from chloramine in potable water by means of high-performance liquid chromatography (HPLC); a detection limit of \(4 \times 10^{-6}\) M dichloramine is possible by use of the polypyrrole–mercury film–glassy carbon electrode.\(^{47}\)

Slater et al.\(^{48}\) have devised sensors consisting of platinum microband-electrode arrays coated with polypyrrole (or an alkylated polypyrrole). When such a detector is exposed to the vapors of an alcohol, molecules of the alcohol permeate the polymer, causing the polypyrrole film to swell and to undergo a change in conductivity. Time-resolved measurement of the change in conductivity of the polypyrrole sensors was used to separate and classify methanol, ethanol, and propanol vapors.

### 3.2 Metal Ion-containing Polymers

Several strategies can be employed to incorporate electroactive transition-metal sites into polymer films on electrodes; these kinds of polymer films are often referred to as redox polymers, although this terminology can also embrace polymer films bearing electroactive organic groups (e.g. naphthacene, anthracene, or viologen). First, it is possible to polymerize onto the surface of an electrode a monomer in which the transition-metal site is covalently bonded to the polymerizable moiety; a classic example is vinylferrocene, which gives rise to poly(vinylferrocene) (3).\(^{49}\) Second, the monomer to be polymerized can consist of a transition-metal complex coordinately linked to the polymerizable moiety; an example of such a monomer is [Ru(bpy)\(_2\)(vbpy)]\(^{2+}\) (where vbpy denotes 4-methyl-2,2',bipyridine and bpy denotes 2,2'-bipyridine) which forms poly[Ru(bpy)\(_2\)(vbpy)]\(^{2+}\) (4).\(^{50}\) Third, a transition-metal complex can be coordinately linked to a polymer after the polymer has been deposited onto an electrode; an example is the interaction of [Ru(NH\(_3\))\(_5\)OH\(_2\)]\(^{2+}\) with a pyridine moiety of a film of poly(4-vinylpyridine) (PVP) (5).\(^{51}\)

Fourth, an ion-exchange polymer can be coated onto an electrode, and the fixed charged sites (cationic or anionic) electrostatically interact with a metal complex; an example is the attachment of [Ru(bpy)\(_3\)]\(^{2+}\) to sulfonate groups of Nafion\(^\circ\), a perfluorinated polysulfonated ion-exchange polymer. Only the first three kinds of redox polymers will be discussed further in this section; films of ion-exchange polymers on electrodes are described in section 3.3.
Before leaving this discussion, we should mention a few other ways to immobilize electroactive transition-metal sites onto electrode surfaces, although these approaches do not strictly involve polymer-coated electrodes. One method\(^{52}\) entails adsorption of a molecule with an extended \(\pi\)-electron system (e.g. 1-(9-phenanthrene)-2-(4-pyridine)ethene) onto a suitable electrode (e.g. pyrolytic graphite or glassy carbon); then an appropriately substituted transition-metal species (e.g. \([\text{Ru(NH}_3]_5\text{OH}_2]^{2+}\)) is coordinately linked to the adsorbate. In another approach, a functionalized silane (e.g. 4-\([\beta\)-(trichlorosilyl)ethyl]pyridine) is attached to an electrode possessing surface hydroxy groups (e.g. Pt-OH), after which a transition-metal complex (e.g. \([\text{Ru(bpy)}_2(\text{DME})\text{Cl}]^{2+}\), where DME denotes dimethoxyethyl) is bonded to the functionalized (pyridyl) end of the silane.\(^{53}\) In addition, one can functionalize the surface groups on edge planes of pyrolytic graphite by treating the graphite with a suitable reagent (e.g. thionyl chloride or cyanuric chloride); subsequent reaction with tetra(aminophenyl)porphyrin, followed by metallation of the porphyrin, completes the process.\(^{54}\)

Many aspects of redox polymers bearing electroactive transition-metal sites, as well as other features of chemically modified electrodes, have been reviewed by Abruná.\(^{55}\)

### 3.2.1 Types of Materials Used

Three examples of polymerizable species with covalently bonded transition-metal sites are (a) the aforementioned vinylferrocene (which can be polymerized onto platinum), (b) \(N\)-(2-ferrocenylyethyl)pyrrole \(6\) (which can be copolymerized with pyrrole to produce a ferrocene-containing polypyrrole film on platinum),\(^{56}\) and (c) \(N,N\)-bis-[3-(pyrrolyl-1-yl)propyl]ferrocene-1,1'-dicarboxamide \(7\) (which can be polymerized onto glassy carbon).\(^{57}\)

![Image](image_url)

We now turn our attention to electrodes coated with polymer films bearing coordinately linked redox-active transition-metal sites; the transition metal can be (a) part of the original molecule (monomer) from which the polymer film is created or (b) introduced after the polymer film has been deposited onto the surface of the electrode.

Included in the first subclass are monomers having metal-containing ligands bound to pyrrole.\(^{58}\) One example is \([\text{Ru(bpy)}_2\text{L}_2]^{2+}\), where \(L\) is 4-(2-pyryl-1-ethyl)-4' -methyl-2,2'-bipyridine, which can be anodically polymerized onto a platinum electrode; when either ferrocene or decamethyl ferrocene permeates the polymer film, there can be direct oxidation at the underlying platinum or catalytic oxidation by electrogenerated ruthenium(III) sites.\(^{59}\) A second example is a nickel(II) pyridyltritolylporphyrin linked to \(N\)-(3-propyl)pyrrole; the resulting compound \(8\) can be oxidatively polymerized onto platinum, and the resulting polymer film exhibits both reversible oxidation and reduction processes.\(^{60}\)

There has been much additional research dealing with polymer films that are formed from monomers with already incorporated transition-metal sites. Earlier we mentioned work\(^{61}\) in which the monomer \([\text{Ru(bpy)}_2\text{vbpy}]^{2+}\) can be reductively polymerized to form poly[\(\text{Ru(bpy)}_2\text{vbpy}\)]\(^{2+}\) on platinum, glassy carbon, tin oxide, and titanium oxide electrodes; in the same study, related monomers containing ruthenium or iron were polymerized, and it was shown that pairs of such monomers can yield site-mixed copolymers as well as spatially segregated two-layer films. Glassy carbon electrodes dip-coated with aquobis(bpy)(poly-4-vinylpyridine)ruthenium(II) have been used by Samuels and Meyer\(^{62}\) as a way to generate immobilized ruthenium(IV) sites for the catalytic oxidation of 2-propanol. Anodic polymerization of cobalt- and nickel-containing tetrakis(o-, m-, and p-aminophenyl)porphyrin, tetrakis(p-(dimethylamino)phenyl)porphyrin, tetrakis(p-hydroxyphenyl)porphyrin, and tetrakis(p-N-pyrylophenyl)porphyrin onto platinum has been described;\(^{62}\) a film of electropolymerized cobalt tetrakis(o-aminophenyl)porphyrin catalyzes the reduction of oxygen. Electroreductive polymerization of \([\text{Fe(vbpy)}]^{2+}\) and \([\text{Ru}(4,4'\text{-dimethyl-bpy})_2(\text{vbpy})]^{2+}\) has been accomplished.
at a platinum cathode; emphasis was placed on the structure of the polymers and their mechanism of formation.\(^{69}\) When a copolymer consisting of 1-vinyl-2-pyrrolidone and meso-[tri(phenyl)mono\((p\)-methacrylamidophenyl)\]porphine is treated with iron(II), the resulting solid can be dissolved in tetrahydrofuran (THF), and the solution can be applied to the surface of a graphite electrode; evaporation of the solvent gives a coated electrode with redox-active iron sites that catalyze the reduction of oxygen.\(^{64}\) Treatment of poly-N-vinylimidazole (pvnvi) with \([\text{Ru(bpy)}_2\text{Cl}_2]\) gives several metallopolymers, such as \([\text{Ru(bpy)}_2\text{(pvnvi)}]^{2+}\) and \([\text{Ru(bpy)}_2\text{(pvnvi)}]\text{Cl}^{+}\), which can be coated onto carbon electrodes.\(^{65}\)

For the second subclass, for which an electroactive transition-metal species is introduced after the polymer is deposited onto an electrode, we will cite just two representative examples. Oyama and Anson\(^{51}\) dip-coated pyrolytic graphite with films of PVP or polyacrylonitrile (PAN), and demonstrated that ruthenium(III)(edta)OH\(_2\) (where edta is ethylenediaminetetraacetate) loses H\(_2\)O in coordinating to a pendant pyridine group of PVP and that \([\text{Ru(NH}_3]_2\text{OH}_2]\text{Cl}^{2+}\) loses H\(_2\)O in binding to a –CN moiety of PAN; in addition, the interaction of \([\text{Ru(NH}_3]_2\text{OH}_2]\text{Cl}^{2+}\) with a film consisting of a mixture of PVP and PAN was examined. Platinum electrodes coated with \(p\)-chlorosulfonated polystyrene have been treated with polyppyridyl complexes of iron, ruthenium, and osmium as well as a ferrocene derivative, a nickel macrocycle, and a nickel porphyrin;\(^{66}\) these inorganic species possess unbound amine, hydroxy, and carboxylate moieties that can react with the \(p\)-chlorosulfonated polystyrene to anchor the redox-active transition-metal complex to the polymer.

As a final group of metal-containing species that can be used to modify an electrode surface, metal phthalocyanines (9) and metal salens (10) deserve some mention.

Over the years, metal phthalocyanines have received much attention as catalysts for the reduction of oxygen. Films of polypyrrole and polyaniline, each intercalated with tetrasulfonated iron phthalocyanine, have been electrodeposited onto gold; these chemically modified electrodes appear to catalyze the reduction of oxygen to water.\(^{67}\) In addition, the reduction of oxygen has been examined at pyrolytic graphite electrodes spin-coated with a number of different metal phthalocyanines,\(^{68}\) and at highly oriented pyrolytic graphite electrodes with adsorbed layers of iron and cobalt crown phthalocyanines.\(^{69}\) Furthermore, oxidative electropolymerization of cobalt and nickel tetraamino-phthalocyanines onto glassy carbon electrodes has been accomplished.\(^{70}\) Metal salen complexes are distinguished by the fact that the ligand (a Schiff base) which coordinates the metal cation can be oxidatively polymerized onto a variety of electrodes; thus, the resulting polymers are conductive (due to their extended \(\pi\)-conjugated systems) as well as redox-active (due to the presence of a transition metal). A number of investigators have studied the formation and properties of anodically polymerized films of metal salens.\(^{71–74}\)

### 3.2.2 Methods of Preparation

As the preceding section has revealed, metal ion-containing polymers on electrodes have been prepared in many ways.\(^{55}\) Anodic or cathodic electropolymerization of a metal-containing monomer onto an appropriate electrode is the most common and straightforward procedure, and many of the references cited above provide details.\(^{49,50,56–60,62,63,70–74}\) Usually, it is most convenient to carry out the direct electropolymerization by means of cyclic voltammetry, because the thickness of the polymer film can be controlled by the number of consecutive scans and by the scan rate; an excellent example of this technique is provided by Figure 3, which depicts the oxidative polymerization of copper(II) salen onto a platinum electrode.\(^{72}\)

Other methods of preparing metal-containing polymer films on electrodes include metallation of an already electrodeposited polymer film;\(^{51}\) adsorption of an organic species, followed by metallation;\(^{52}\) attachment of a complexing ligand via silanization, followed by metallation;\(^{53}\) functionalization of edge-plane sites of graphite, followed by reaction with a complexing ligand and introduction of a metal ion;\(^{54}\) dip-coating of an electrode with a metallated polymer;\(^{61,64,65}\) covalent linkage of a functionalized metal-containing species to a functionalized polymer film;\(^{66}\) intercalation of a polymer with a metal-containing compound;\(^{67}\) spin-coating of an electrode with a metal-containing species;\(^{68}\) and adsorption of a metallated compound.\(^{69}\)

### 3.2.3 Methods of Characterization

Virtually all of the electrochemical and spectroscopic techniques referred to in section 3.1.3 are suitable for
are 0.11, 0.15, and 0.60 ppm, respectively. A sensor has been developed that utilizes a glassy carbon electrode dip-coated with [Ru(bpy)3Cl2]Cl for the flow injection measurement of nitrite; this procedure has been applied to the determination of nitrate in fertilizer, after the nitrate in the sample is first converted to nitrite with the aid of a copper–cadmium reductor.

A carbon electrode bearing a film of anodically polymerized tetraaminophthalocyanatocobalt(II) responds potentiometrically in a Nernstian fashion to sulfide ion (3 × 10⁻⁶ to 10⁻³ M) and to mercaptoethanol (6 × 10⁻⁶ to 10⁻³ M). Amperometric determination of BHA (an antioxidant) has been accomplished with a poly[tetraaminophthalocyanato nickel(II)]-modified glassy carbon electrode; a linear response was observed for the concentration range from 5.6 × 10⁻⁸ to 5.6 × 10⁻⁵ M, and the detection limit was 1.5 × 10⁻⁸ M. Glassy carbon, coated with electropolymerized tetraaminophthalocyanatonickel(II), is a sensor for the determination of dopamine at concentrations from 2 × 10⁻⁷ to 2 × 10⁻⁵ M, with a detection limit of 9 × 10⁻⁹ M; one can eliminate the interference due to ascorbic acid by coating the modified electrode with a layer of Nafion®.

3.3 Ion-exchange Polymers

As mentioned previously, Nafion® (11) is a perfluorinated, polysulfonated cation-exchange polymer.

\[
\text{-(CF}_2\text{CF}_2)_n\text{-(CFCF}_2)_m
\]

(11)

One can purchase Nafion®, in its protonated form, as a dilute solution of the polymer in alcohol–water. A measured small volume of this solution can be applied to the surface of a glassy carbon electrode; then, after the solvent has evaporated, a film of the polymer adheres to the electrode. This coated electrode can be soaked in an appropriate electrolyte solution (e.g. dilute sulfuric acid), and can then be inserted into an electrochemical cell containing a solution of some cationic metal complex (e.g. [Ru(bpy)3]²⁺) along with the same supporting electrolyte. Quickly, the [Ru(bpy)3]²⁺ becomes incorporated into the polymer film via a cation-exchange process (two protons at two adjacent –SO₃⁻ sites are replaced by one [Ru(bpy)3]²⁺ moiety) until a steady state is attained, whereupon a variety of electroanalytical measurements can be performed. One can employ an alternative approach, which involves preloading the Nafion® with...
been proposed as a coating that can bind cations, oxo-bridged dimers. In addition, poly(vinyl sulfate) has bind catalytically active, cationic ruthenium and osmium convert the

When a pyrolytic carbon electrode filmed with deprotonated polyanionic acid is placed into a solution of $[\text{Ru(NH}_3)_6]^{3+}$, the $-\text{COO}^-$ sites can electrostatically bind the positively charged metal complex. Another approach taken by Vining and Meyer involved coating glassy carbon electrodes with $p$-chlorosulfonated polystyrene; then the polymer-filmed electrode was exposed to an aqueous medium of pH 9 in order to convert the $\text{SO}_2\text{Cl}$ sites to $\text{SO}_3^-$ sites which can bind catalytically active, cationic ruthenium and osmium oxo-bridged dimers. In addition, poly(vinyl sulfate) has been proposed as a coating that can bind cations, including $[\text{Ru(NH}_3)_6]^{3+}$, $[\text{Ru(bpy)}_3]^{2+}$, $[\text{Co(bpy)}_3]^{3+}$, and $[\text{Co(phen)}_3]^{3+}$. A mixture of a cystine-derivatized pyrrole and a tetraethylammonium-substituted pyrrole can be oxidatively copolymerized onto platinum or glassy carbon electrodes; chemical treatment of the polymer-coated electrode with dithiothreitol converts the polymer to its cysteine-SH form which tightly binds $[\text{Fe}_{2}\text{S}_{2}]^{2+}$ centers to give an electrode–polymer assembly with electroactive, cysteinyl-ligated, ferredoxin-like units. Carbon electrodes coated with Eastman Kodak AQ 55 (a polysulfonated block copolymer) incorporate and strongly retain electroactive counter-cations (e.g. $[\text{Ru(1,10-phenanthroline)}_3]^{2+}$ and $[\text{Ru(9,10-phenanthroline-5,6-dione)}_3]^{2+}$) in aqueous and acetonitrile solutions.

Electrodes coated with anion-exchange polymers that can electrostatically bind anionic metal complexes have received considerable attention. Oyama and Anson demonstrated that graphite electrodes filmed with protonated PVP can strongly bind multiply charged anions such as $[\text{Fe(CN)}_6]^{3-}$ and $[\text{IrCl}_6]^{2-}$. Methyl- or benzyl-quaternized PVP provides a poly-electrolyte coating for graphite that is superior to PVP, because the density of cationic sites available for anion binding is independent of pH. Protonated poly(L-lysine), coated onto a freshly cleaved graphite electrode, has been shown to interact electrostatically with both $[\text{Fe(III)(edta)}]^-$ and $[\text{Fe(II)(edta)}]^2-$, and a model to explain charge propagation through the film has been proposed. A platinum electrode coated with poly[5,15-bis(2-aminophenyl)porphyrin], with and without metallation by cobalt(II), responds potentiometrically at pH 5.5 to a variety of anions, including iodide, bromide, fluoride, thiocyanate, salicylate, nitrate, and acetate. An interesting new derivative of polyaacetylene with pendant cationic moieties – namely, poly(dihexyldipropargyl ammonium bromide) – has been synthesized and has been coated (as a mixed film with Nafion®) onto an ITO electrode; however, its binding of anionic transition-metal complexes has not yet been explored.

### 3.3.1 Types of Materials Used

Both cationic and anionic ion-exchange polymer films have been coated onto electrodes. Despite the overwhelming popularity of Nafion®, several other types of cation-exchange polymers have been employed. Majda and Faulkner used platinum electrodes spin-coated with the sodium salt of poly(styrene sulfonate) to investigate the electrochemistry of incorporated $[\text{Ru(bpy)}_3]^{2+}$. When a pyrolytic carbon electrode filmed with deprotonated polyanionic acid is placed into a solution of $[\text{Ru(NH}_3)_6]^{3+}$, the $-\text{COO}^-$ sites can electrostatically bind the positively charged metal complex. Another approach taken by Vining and Meyer involved coating glassy carbon electrodes with $p$-chlorosulfonated polystyrene; then the polymer-filmed electrode was exposed to an aqueous medium of pH 9 in order to convert the $\text{SO}_2\text{Cl}$ sites to $\text{SO}_3^-$ sites which can bind catalytically active, cationic ruthenium and osmium oxo-bridged dimers. In addition, poly(vinyl sulfate) has been proposed as a coating that can bind cations, including $[\text{Ru(NH}_3)_6]^{3+}$, $[\text{Ru(bpy)}_3]^{2+}$, $[\text{Co(bpy)}_3]^{3+}$, and $[\text{Co(phen)}_3]^{3+}$. A mixture of a cystine-derivatized pyrrole and a tetraethylammonium-substituted pyrrole can be oxidatively copolymerized onto platinum or glassy carbon electrodes; chemical treatment of the polymer-coated electrode with dithiothreitol converts the polymer to its cysteine-SH form which tightly binds $[\text{Fe}_{2}\text{S}_{2}]^{2+}$ centers to give an electrode–polymer assembly with electroactive, cysteinyl-ligated, ferredoxin-like units. Carbon electrodes coated with Eastman Kodak AQ 55 (a polysulfonated block copolymer) incorporate and strongly retain electroactive counter-cations (e.g. $[\text{Ru(1,10-phenanthroline)}_3]^{2+}$ and $[\text{Ru(9,10-phenanthroline-5,6-dione)}_3]^{2+}$) in aqueous and acetonitrile solutions.

Electrodes coated with anion-exchange polymers that can electrostatically bind anionic metal complexes have received considerable attention. Oyama and Anson demonstrated that graphite electrodes filmed with protonated PVP can strongly bind multiply charged anions such as $[\text{Fe(CN)}_6]^{3-}$ and $[\text{IrCl}_6]^{2-}$. Methyl- or benzyl-quaternized PVP provides a poly-electrolyte coating for graphite that is superior to PVP, because the density of cationic sites available for anion binding is independent of pH. Protonated poly(L-lysine), coated onto a freshly cleaved graphite electrode, has been shown to interact electrostatically with both $[\text{Fe(III)(edta)}]^-$ and $[\text{Fe(II)(edta)}]^2-$, and a model to explain charge propagation through the film has been proposed. A platinum electrode coated with poly[5,15-bis(2-aminophenyl)porphyrin], with and without metallation by cobalt(II), responds potentiometrically at pH 5.5 to a variety of anions, including iodide, bromide, fluoride, thiocyanate, salicylate, nitrate, and acetate. An interesting new derivative of polyaacetylene with pendant cationic moieties – namely, poly(dihexyldipropargyl ammonium bromide) – has been synthesized and has been coated (as a mixed film with Nafion®) onto an ITO electrode; however, its binding of anionic transition-metal complexes has not yet been explored.

### 3.3.2 Methods of Preparation

By far the most common methods to prepare electrodes with films of ion-exchange polymers are the techniques of dip-coating, drop-coating, and spin-coating. These procedures are literally self-explanatory, but details can be found in the various references cited in the preceding section. Brumlik et al. have described a new approach for the fabrication of sulfonated fluorochlorocarbon ionomer films on surfaces of stainless steel and microporous alumina, which entails the radiofrequency plasma polymerization of trifluoroacetylethylene (TFCE) and trifluoromethane sulfonic acid (TFMSA); this technique offers the advantage of providing anion-exchange polymers that are not commercially available, and so it deserves attention by electroanalytical chemists.

### 3.3.3 Methods of Characterization

As for other previously described kinds of selective coatings on electrodes, the same methods of characterization (including all of the electroanalytical techniques) outlined in sections 2.3 and 3.1.3 can be employed for surfaces coated with films of ion-exchange polymers. In addition, some of the references cited in section 3.1.1 provide valuable insights. In particular: film thicknesses have been measured; diffuse-reflectance Fourier transform infrared (FTIR) spectroscopy has been used to characterize a polymer; the quantities of electrostatically bound transition-metal species have been determined spectrophotometrically through the use of optically transparent, polymer-coated electrodes; the electrical conductivities of polymer films, along with their absorption, fluorescence, electron paramagnetic resonance (EPR), and X-ray diffraction spectra, have been determined and SEM and XPS of polymer films have proven to be useful.
3.3.4 Analytical Applications

Electrodes coated with ion-exchange polymers, especially Nafion®, have been employed for many different kinds of electrochemical studies, including electroanalysis. In some applications the purpose of a Nafion® film has been to provide or to improve selectivity toward one or more specific analytes, whereas in other instances a Nafion® film has served to protect some other coating on the surface of an electrode.

To alleviate problems associated with an adventitious surfactant (alkaline phosphatase) during the adsorptive stripping voltammetric determination of copper(II) at the 10 nM concentration level, Economou and Fielden used Nafion® to coat a mercury-filmed glassy carbon electrode. In a method for the measurement of copper(II) in natural waters, a carbon electrode, first coated with a complexing agent (1-phenyl-3-methyl-4-octanoylpyrazole-5-one), was subsequently modified with a Nafion® film; the procedure is successful for the determination of nanomolar to micromolar concentrations of copper(II), with a relative standard deviation of 1–6%. Lead(II) has a detection limit of 20 nM to 50 µM, determined by square-wave voltammetry with a relative standard deviation of 1–6%. Lead(II) has been measured by means of square-wave voltammetry with a glassy carbon electrode modified with a mercury film coated with Nafion® that contains 2,2'-bipyridine; for a 5-min preconcentration step, the anodic stripping method gives a calibration curve for lead(II) that is linear from approximately 2 × 10⁻⁸ to 2 × 10⁻⁵ M, with a detection limit of 2 × 10⁻⁹ M.

A Nafion®-coated glassy carbon electrode, treated with ruthenium(III), can be employed as an amperometric sensor for the determination of hydrazine, dimethylhydrazine, and phenylhydrazine in drinking and river waters; the method provides a linear response for hydrazine in the range of 1.8 × 10⁻⁷ to 4.6 × 10⁻⁴ M, with a detection limit of 1.0 × 10⁻⁷ M, and similar analytical results can be achieved with the other hydrazines. A method for the amperometric determination of nitric oxide has been devised that utilizes an ultramicroelectrode chemically modified with a film of poly[nickel(II) salen] and Nafion®; the electrode responds linearly to dissolved oxygen at concentrations ranging from 1 to 10 ppm in both acidic and alkaline environments. Finally, nanoelectrode ensembles films with Eastman Kodak AQ 55 (a polysulfonated block copolymer) have been studied by Ugo et al. In separate experiments, ferrocenyldimethyltrimethylammonium cation and [Ru(NH₃)₆]³⁺ were preconcentrated (partitioned) into these modified electrodes, and the cyclic voltammetric response for each system was measured. For the first cation, linear calibration curves for concentrations ranging from 20 nM to 50 µM were obtained (with a detection limit of 5 nM), and similar results were achieved for [Ru(NH₃)₆]³⁺ (with a detection limit of 1 nM). This approach to highly sensitive analysis merits extension to systems containing other cations.

4 LANGMUIR–BLODGETT FILMS ON ELECTRODES

For many types of electrode coatings, the dual nature of surfactants plays a key role. In the language of Langmuir–Blodgett films, the surfactant molecule is termed an “amphiphile” and is mechanically forced into an organized monolayer within a liquid/gas interface. Typically, one accomplishes this by preparing a dilute solution (~1%) of pure amphiphile(s) in a solvent of high vapor pressure (e.g., chloroform). Aliquots of this solution are then allowed to evaporate over a liquid (the subphase) in which the amphiphiles as a whole are insoluble. Usually, the subphase consists of purified water of controlled pH and ionic strength, but mercury, glycerol, hydrocarbons, and other liquids have been employed as well. After the volatile solvent evaporates, the amphiphiles are in a state known as a two-dimensional gas in which they are widely and randomly distributed along the surface of the subphase. With aqueous subphases, the amphiphiles are oriented with their hydrophilic regions immersed, forcing hydrophobic side chains up and out of the water. As shown in Figure 4, the two-dimensional gas and subphase are contained in a specially designed (commercially available) trough with a movable barrier traversing the interface.

At this stage, the barrier is then moved along the trough to force the amphiphiles into successively more ordered states, while the surface pressure and area per molecule are recorded. A pressure–area isotherm results which frequently displays marked phase transitions. A theoretical isotherm for stearic acid on 0.01 M hydrochloric acid, depicted in Figure 5, illustrates the various phases of film formation.

If the area of a solid-phase film is decreased further by the movable barrier, a sharp decline in surface pressure results, indicating buckling of the monolayer and the
formation of multilayer structures. For the purposes of electrode coatings, such films are to be avoided since they are not reproducible, and multilayer coatings on electrodes can easily be achieved through the repeated application of monolayers.

4.1 Types of Materials Used

A wide variety of molecular structures can be incorporated into Langmuir–Blodgett films. DeArmond and Fried102 and Goldenberg103 have summarized much of the work that has been done with electroactive amphiphiles (which usually must be synthesized). Space limitations preclude a detailed discussion of these species, but some noteworthy examples include derivatized fullerenes, tetrathiafulvalenes (TTFs), quinones, and various metal-containing complexes such as porphyrins, phthalocyanines, cyclams, bipyridine complexes, and metallocenes. In addition, several polymerizable amphiphiles have been employed in electrode films. With these species, polymerization may be initiated either before or after transfer of the monolayer to the electrode, a feature which is unique to the Langmuir–Blodgett method.

In some applications, the amphiphile need not be electroactive, in which case a very large array of molecules may be employed for a Langmuir–Blodgett film. Hann101 has provided detailed coverage of many of these species: long-chain (C₁₆ or higher) fatty acids and their various derivatives comprise the largest and most well studied class. For biological applications, phospholipids and sterols are most commonly employed.104

4.2 Methods of Preparation

Once an ordered monolayer has been formed, it must be transferred onto an electrode surface; the method employed for this transfer depends on the shape and wetting characteristics of the electrode surface. For planar electrodes, transfer may be accomplished in two ways. First, but less well understood, is the method involving vertical immersion and emersion of the electrode through the interface. Figure 6 illustrates how this method was recently applied to the coating of optically transparent ITO electrodes.105,106

In the first stage of the process, the ITO electrode (a hydrophilic substrate) penetrates an ordered monolayer on water from above. Formation of an upward-curving meniscus prevents the amphiphiles from adsorbing as the electrode is immersed. Slow emersion of the electrode from the subphase then takes place (5 mm min⁻¹), as the surface pressure is maintained constant by the movable barrier. If the substrate is sufficiently smooth, water will drain away and evaporate from the surface of the electrode as an even monolayer is transferred. Reimmersion of such an electrode into the interface can then be used to produce bilayers and multilayers whose structures closely resemble those of biological cell membranes.104 One can make a preliminary evaluation of the quality and quantity of film transferred by simply comparing the area of the

![Figure 6](image_url)
electrode to the change in area of the trough as dictated by the barrier (the transfer ratio).\(^{[107]}\)

Alternatively, or if the electrode is not conveniently submerged, a horizontal-lifting method of transfer may be employed. Figure 7 illustrates how this procedure (Schaefer’s method) has been applied to the coating of freshly cleaned (hydrophobic) glassy carbon electrodes.\(^{[108,109]}\)

One coats the electrode by simply lowering it onto a monolayer parallel with the surface. Following reversed-phase adsorption of the film, the electrode is either withdrawn with a monolayer (or bilayer)\(^{[102]}\) intact on its surface or held at the interface as excess monolayer is swept away. In the former case, recompression of the interface by means of the movable barrier generates a new ordered monolayer.

To perform electrochemical examination of the film, it is necessary to transfer the electrode to a different solution. In some cases, however, withdrawal of the electrode from the subphase is unnecessary, and the electrochemistry can be done in situ. In these experiments, counter- and reference electrodes are pre-positioned in a subphase containing a suitable electrolyte. So-called “horizontal-touch” techniques have been successfully employed with both glassy carbon\(^{[110]}\) and ITO\(^{[111]}\) electrodes.

Horizontal transfers avoid the surface flow of the monolayer inherent with vertical methods, and thus can preserve the original structure of the monolayer to a larger degree. Furthermore, surface-pressure requirements are much less stringent, making the technique applicable to a wider variety of amphiphiles.\(^{[111]}\)

Nelson and Benton\(^{[112]}\) described a vertical-type procedure for the preparation of a spherical hanging mercury drop electrode (HMDE) modified with a monolayer of naturally occurring phospholipids. In this case, film deposition occurs during the immersion step, with the long alkyl chains of the lipids next to the mercury.

As a consequence of their formation and structure, Langmuir–Blodgett films exhibit several clear advantages over other electrode coatings in terms of flexibility, ease of application, and sensitivity. First, one can easily make mixed films in any proportion by combining the appropriate ratio of one amphiphile with another in the evaporated solvent. As long as the amphiphiles are miscible with one another, the resulting films will have a large degree of homogeneity with no dependence on competing chemical reactions (as with mixed SAMs and copolymers). Second, the Langmuir–Blodgett technique allows one to prepare both highly ordered and multiply layered coatings on electrodes; the number of discrete layers can range from one to as many as 50. Third, the monolayer approach is very efficient, consuming only tiny quantities of synthetic amphiphiles,\(^{[111]}\) while exposing the vast majority of these molecules to electroanalysis. Expensive amphiphiles can be further conserved by being mixed with well behaved long-chain carboxylic acids.\(^{[108]}\)

Casting and bulk polymerization methods tend to be far more wasteful. Fourth, several manufacturers offer fully automated, programmable-trough instruments, enabling one to prepare films with little operator involvement. Some of these are even equipped with multiple troughs, allowing one to prepare alternate-layered electrodes.

For some Langmuir–Blodgett films, a possible disadvantage lies in the fact that they are inherently less stable than other electrode coatings. Inclusion of solvent during deposition of a Langmuir–Blodgett film can lead to its post-transfer instability; evaporation of solvent trapped in irregularities or imperfections on the surface can cause collapse of the monolayer.\(^{[101]}\) Another problem is that forming the film and transferring it to the surface of an electrode are both very time-consuming processes.

### 4.3 Methods of Characterization

An excellent summary of the nonelectrochemical techniques employed to characterize Langmuir–Blodgett and other organic thin films has been written by Ulman.\(^{[113]}\) One of the most powerful techniques that can be applied in situ involves optical second harmonic generation (SHG). This method has been reviewed by Corn\(^{[114]}\) and by Richmond,\(^{[115]}\) and features submonolayer sensitivities, instantaneous response time, the ability to discriminate between surface and bulk species, and access

---

to both film thickness and orientation. Although Langmuir–Blodgett films adhere relatively weakly to electrode surfaces, many are still amenable to all standard surface analyses requiring high vacuum. One recent example included the secondary ion mass spectrometric analysis of cadmium arachidate films on various metal substrates, with little or no sample preparation being required.\(^{116}\)

### 4.4 Analytical Applications

Although electroanalytical applications for Langmuir–Blodgett films are largely unrealized, it is clear that electrochemical research in this area has only just begun. Many reports have focused either on the dynamic transport of electroactive species across a bilayer membrane or on the enzymatic generation of electroactive species at the surface of a modified electrode. Results from these systems are included in section 5 below.

Nelson\(^{117}\) prepared phosphatidylserine-coated mercury electrodes (HMDEs) to study the reduction of Tl\(^{+}\), Cd\(^{2+}\), Cu\(^{2+}\), Pb\(^{2+}\), and Eu\(^{3+}\) in aqueous systems. It was found that the organization of the film is potential dependent and that the reduction potentials of the various metal ions depend strongly on the extent of film protonation (pH) and the presence of other metal species. Nelson et al.\(^{118}\) observed that a variety of common aqueous pollutants, including polynuclear aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs) and various pesticides, can be concentrated from contaminated water samples into dioleoylphospholipid monolayers on mercury; for PAHs, these investigators established that the detection limit is 0.4 µg L\(^{-1}\), with a relative standard deviation of 7%.

In a unique application of the Langmuir–Blodgett technique, Fujihira and Poosititsak\(^{109}\) employed a glassy carbon electrode filmed with an electroactive bipyridinium amphiphile and coated with platinum. This two-layer electrode catalyzed the reduction of oxygen when used for rotating-disk voltammetry, a fact which simultaneously attests to the versatility and stability of Langmuir–Blodgett films.

Finally, Miller and Bard\(^{111}\) designed a special trough to accommodate the filming of a small horizontally oriented ITO electrode. They demonstrated picomole sensitivities of this electrode toward alkylated [Ru(bpy)]\(^{3+}\) species, noting that the current efficiency for the Langmuir–Blodgett method far exceeds that attainable by traditional casting methods with the same complexes.

### 5 IMMOBILIZED ENZYMES ON ELECTRODES

Chemical selectivity remains one of the great challenges facing analytical electrochemists today. In this regard, electrodes modified with enzymes (bioelectrochemical sensors) continue to hold the most promise for progress and are presently one of the most active areas of research in electrochemistry.\(^{119–122}\) Over 3300 references (in English) from 1987 to mid-1999 were retrieved on this subject from the Institute of Scientific Information database alone.\(^{123}\) These reports cover a host of enzymes (from multiple sources) and immobilization techniques for virtually every type of electrode. Common themes include (a) the effect of various deposition processes on the activity and stability of the enzyme(s), (b) the influence of any mediators and/or required cofactors on electronic communication between the enzyme and the electrode, (c) the sensitivity and selectivity of the modified electrode for a given substrate (especially within a complex matrix), (d) the effect of polymers, membranes, and various other supports on the performance of the electrode system, and (e) the overall stability and applicability of the modified electrode system. With this in mind, our goal is merely to provide the reader with an entry point into the literature of enzyme-modified electrodes along with only the most basic of overviews.

#### 5.1 Types of Materials and Methods of Preparation

Although enzymes typically do not exhibit reversible redox behavior at bare electrodes, they frequently do when immobilized in polymers, membranes, cross-linked networks, and a host of other media. Reasons for this behavior have been discussed by several authors.\(^{124,125}\) In addition, it is usually necessary to employ “mediators” (small, organic, electron-transfer partners) to establish electronic communication between the electrode and the immobilized enzyme. Figure 8 illustrates a general scheme that applies to an electrode modified with an oxidase.

Usually, the link between electrode and enzyme is achieved with a combination of a synthetic mediator and an enzyme cofactor (e.g. reduced forms of nicotinamide adenine dinucleotide or flavin adenine dinucleotide). Enzyme-modified electrodes of all kinds are prepared from aqueous starting materials, but are not restricted to use in aqueous media.\(^{126}\) A brief overview of some common materials and methods for the construction of enzyme-modified electrodes follows. Although this list is

---

**Figure 8** General format of an electrode modified with an oxidase and mediator(s).
far from complete, recent examples and reviews therein should serve as an adequate starting point.

5.1.1 Enzymes and Mediators
Glucose sensors based on GOx derived from Aspergillus niger form the cornerstone of enzyme research in electrochemistry. Reports featuring a new bioelectrochemical sensor design typically employ GOx as a benchmark for the performance of the electrode – usually one notes the effect of ascorbate and uric acid since these are problematic interferents found in serum samples. Additional commonly employed enzymes include other oxidases (especially horseradish peroxidase), dehydrogenases, cytochromes, and myoglobins. For systems with synthetic mediators, derivatives of ferrocene appear to be the most common, but tetracyanoquinodimethane complexes are also frequently employed. Enzymes and any other added reagents) within the bulk of the polymer film, which can also serve as part of the transduction mechanism. For example, the conductivity of polypyrrole is pH sensitive, so it is the medium of choice for enzyme-substrate interactions which proceed with a net change in pH. Applications of electroactive polymers (and incorporated mediators) to enzyme-modified electrodes have been reviewed.

5.1.2 Polymers for Electrodeposition
Electroactive polymers provide the experimenter with a rapid and simple method for the immobilization of enzymes onto an electrode surface. Pyrroles and aromatic amines (especially diamines) are the most commonly employed monomers and may be polymerized onto an electrode from an aqueous solution containing the enzyme of interest. This results in the entrapment of enzymes (and any other added reagents) within the bulk of the polymer film, which can also serve as a part of the transduction mechanism. For example, the conductivity of polypyrrole is pH sensitive, so it is the medium of choice for enzyme-substrate interactions which proceed with a net change in pH. Applications of electroactive polymers (and incorporated mediators) to enzyme-modified electrodes have been reviewed.

5.1.3 Chemical Cross-linking
Glutaraldehyde can be employed for the chemical cross-linking of enzymes in solution. Typically, a mixture of enzyme(s), mediator(s), and a frequently a stabilizer (such as bovine serum albumin (BSA)) is treated with glutaraldehyde and then cast onto an electrode surface. A recent paper by Sarkar et al. illustrates the use of glutaraldehyde in an amino acid sensor based on screen-printed carbon electrodes. Cross-linking and polymeric supports are often used either in tandem or sequentially to enhance the stability and selectivity of an electrode. Thus, Moore et al. utilized a mixture of glutaraldehyde, poly(vinyl alcohol), and GOx in a voltammetric sensor for acetaminophen and norepinephrine. Nishizawa et al. prepared layered amperometric sensors for penicillin by coating interdigitated platinum arrays with polypyrrole followed by cross-linking of penicillinase with BSA.

5.1.4 Covalent Attachment
When a glassy carbon electrode is treated with dilute nitric acid and dichromate at positive potentials (+2.2 V versus saturated calomel electrode (SCE)), carboxylic acid functionalities are rapidly formed along the surface. Carbodiimide reagents may then be employed in a two-step synthesis which results in the covalent attachment of an enzyme to the surface (via an amide linkage). Bourdillon et al. have provided an example pertaining to GOx.

5.1.5 Immobilization in Self-assembled Monolayers
Willner and Ricklin recently prepared an amperometric biosensor based on an enzyme covalently attached to both an electron-transfer mediator (pyrroloquinone) and a monolayer of cysteamine on gold. They demonstrated that this configuration is capable of oxidizing the reduced form of nicotinamide adenine dinucleotide in solution, while being oxidized at the electrode, thus linking the electrode to the activity of the enzyme. Willner et al. have summarized other methods pertaining to enzymes on SAMs.

5.1.6 Langmuir–Blodgett Films
Biotinylated phospholipids are readily assembled into monolayer Langmuir–Blodgett films. These films can then be treated with streptavidin-modified enzymes prior to transfer onto an electrode surface. Rehak et al. have employed this technology to prepare a xanthine-selective electrode. Applications of Langmuir–Blodgett films for other biosensors have been reviewed by Osa and Anzai and by Aizawa.

5.1.7 Direct Adsorption
Certain carbon electrode surfaces (such as pyrolytic graphite edge planes) have been shown to adsorb enzymes from solution electrostatically. In some cases, this results in the direct communication of an enzyme with the electrode (allowing for potential-controlled enzyme activity). Using this approach, Hirst et al. demonstrated a potential-dependent fumarate–succinate equilibrium with succinate dehydrogenase.

5.1.8 Lipid and Surfactant Membranes (Bilayers and Multilayers)
Rusling and Nikolelis et al. have summarized the application of casting techniques to the study
of membrane-bound proteins (especially cytochrome P450cam and myoglobin) on various electrode surfaces. Typically, phospholipids (or other synthetic surfactants) are initially cast onto the electrode surface from a volatile organic solvent (e.g. chloroform). As the solvent evaporates, the surfactant molecules spontaneously form multiple bilayer membranes on the surface. This modified electrode surface is then allowed to equilibrate (~20 min) with an aqueous solution of an enzyme, resulting in the incorporation of the protein into the bilayers. Alternatively, an aqueous vesicular dispersion of pure surfactant(s) is combined with a solution of the enzyme, and the mixture is cast onto the surface. As the water evaporates, vesicles in the mixture collapse, again resulting in the formation of multiple bilayers containing an enzyme. Lipid bilayers provide the enzyme with a more native environment, and so preserve the original structure and activity to a larger degree.

5.1.9 Zeolites and Clays
Recently, it has been demonstrated that certain zeolites and clays (immobilized onto the surfaces of electrodes) can act as effective hosts for both enzymes and electron-transfer mediators. These “reagentless” sensors feature simple construction and enhanced strength, but are essentially restricted to neutral aqueous solutions. Responses to interferents may be diminished with further modifications of the zeolite surface.

5.2 Methods of Characterization
Primary concerns for any enzyme-modified electrode are for the activity and stability of the enzyme. To this end FIA (described elsewhere in this encyclopedia) is ordinarily employed. Response of the electrode to multiple injections over a period of minutes to weeks can indicate whether denaturing or leaching of enzyme or mediator occurs. FIA also affords rapid determination of the limit of detection and linear range, while revealing the response time of the electrode. In addition, known inhibitors and interferents can be introduced into a solution of substrate to show that the enzyme behaves normally and that the initial response can be recovered.

Several standard surface analytical techniques have also been applied to enzyme-modified electrodes. Recent investigations have included XPS, SEM, FTIR spectroscopy, and STM.

5.3 Analytical Applications
Immobilized enzymes impart unprecedented chemical selectivity to virtually any electrode and, in principle, allow for repeated use of the catalysts in continuous processes without contaminating the products. As a result, enzyme-modified electrodes are finding application in the food industry, in clinical pharmacology (especially for glucose, lactate, urea, xanthine, glutamine, and various neurotransmitters), and in environmental chemistry for the detection of pesticides and pollutants.

SELECTIVE ELECTRODE COATINGS FOR ELECTROANALYSIS

1 Introduction

1.1 Definition of Self-assembled Monolayer

An organized SAM is a single layer of molecules on a substrate in which the molecules exhibit a high degree of orientation, molecular order and packing (Figure 1). There are two common methods for depositing a monolayer. In the Langmuir–Blodgett (LB) method, amphiphilic molecules are spread on the air–water interface, compressed laterally, and transferred to the substrate either by dipping the substrate through the interface or by touching it to the interface. In the self-assembly method, the monolayer spontaneously forms upon exposure of the substrate to a solution or vapor containing the molecules. Successful self-assembly requires a relatively strong bond between the substrate and an atom or moiety in the molecule, and an additional lateral interaction between molecules in the monolayer. The strength of the head group–substrate bonds, the lateral interactions and the density of packing result in sufficient stability that the monolayer resists removal by a solvent rinse. Unlike the popular LB monolayers, SAMs remained relatively obscure until the 1980s when several researchers discovered that long-chain thiols and disulfides spontaneously formed remarkably well-packed and stable monolayers on gold substrates. Because SAMs provide a facile means of defining the chemical composition and structure of a surface (see below), they have become the focus of intensive investigation. Potential technological applications can be...
found in areas such as wetting, lubrication, adhesion, corrosion, biocompatibility, catalysis, chemical sensing and nanoscale lithography.

1.2 Types of Self-assembled Monolayers on Electrodes

SAMs have been formed on every common electrode material with the possible exception of carbon. The common electrode metals (gold, silver, platinum and mercury) have all been coated with SAMs containing sulfur compounds, especially thiols, disulfides, and sulfides. The sulfur compounds most commonly contain pendant alkane chains of varying lengths. Less common are SAMs based on adsorption of isonitriles. Chlorosilanes with long alkyl chains self-assemble on doped metal oxides such as SnO$_2$, silicon with a thin oxide coating and even gold without any surface oxide. Generation of alkane radicals near an oxide-free silicon surface results in the formation of a densely packed SAM in which a methylene carbon is directly bonded to a silicon surface atom.

1.3 Advantages of Self-assembled Monolayers Based on Thiols and Related Molecules

The first advantage is the ease with which SAMs are formed when gold and other metals are exposed to thiols and related molecules (in subsequent discussion, the word thiols will also imply disulfides and sulfides). A monolayer is deposited on the metal in a matter of seconds to minutes. The self-assembly method does not require anaerobic or anhydrous conditions; nor does it require a vacuum. Self-assembly is relatively insensitive to the choice of solvent. While organic-free metal surfaces are desirable, the high affinity of the sulfur for the metal enables the assembling layer to displace more weakly adsorbed impurities. Curvature or accessibility of the metal surface is not a factor; substrates can range from macroscopic to submicroscopic, and from smooth to highly porous.

A second advantage arises from the affinity of the sulfur for the metal and the strength of the bond formed. SAMs survive prolonged exposure to vacuum. It is possible to have a wide range of functional groups in the adsorbing molecule without disrupting the self-assembly process or destabilizing the SAM. Considering just the family of $w$-substituted alkanethiols, the terminal substituent can be an alkane (linear, branched, perfluorinated, perdeuterated), alkene, alkyne, aromatic, halide, ether, alcohol, aldehyde, carboxylic acid, amide, ester, amine or nitrile. The “body” of the molecule can contain, for example, heteroatoms, aromatic groups, conjugated unsaturated links and other rigid rod structures, sulfones and amides. If the SAM is uniform in composition and densely packed, then a single functional group is exposed on the external surface. This property permits the exploration of the effect of surface composition on such surface-sensitive properties as wetting, friction and adhesion. The diversity of sulfur-based SAMs, their autophobic behavior and the slow exchange with solution molecules allows the preparation of micropatterned surfaces in which the SAM is laterally heterogeneous.

Mixed SAMs (Figure 2) can be prepared by depositing different molecules simultaneously or sequentially. When
both molecules are present in the deposition solution, the mole fraction of each molecule in the SAM can be controlled via the mole ratio of the two molecules in the solution, the identity and temperature of the solvent and the time of the deposition.\textsuperscript{42} The distribution of the two molecules may vary from intimately mixed to completely phase-separated. It is possible to deposit SAMs with a 1:1 mole ratio of two chains and terminal groups with presumably perfect mixing via asymmetric sulfides or disulfides or thiols with two pendant chains.\textsuperscript{43} In sequential deposition, a second thiol is incorporated into an existing SAM by prolonged immersion of the substrate in the second deposition solution.

In electrochemistry, the utility of thiol-based SAMs arises from their ability to survive the electrochemical experiment. The sulfur atoms resist oxidation, reduction and desorption. SAMs on electrodes are stable over a wide range of potentials and electrolyte compositions (especially aqueous electrolytes). They afford a means of controlling the electrode/electrolyte interfacial properties and the accessibility of the electrode surface to solution molecules. SAMs also provide a means of attaching to the electrode a diverse set of structures ranging from modified monolayers to multilayers. Specific applications include the development of more selective and sensitive electrochemical sensors (especially biosensors), control of faradaic reaction mechanisms, and a better understanding of the factors controlling electron transfer over long distances and under large driving forces.

1.4 Scope and Previous Reviews

The scope of this article will be primarily limited to SAMs composed of thiols and related molecules on metal electrodes. Since there is already a vast literature on the characterization of SAMs on metals, and since the findings therein are relevant to the behavior of SAMs on electrodes, a brief overview of nonelectrochemical characterization of SAMs follows the section on SAM preparation. Postdeposition modification reactions are summarized before discussion of the electrochemical characterization of the SAMs on electrodes. The final section covers a range of electrochemical applications of SAMs.

A previous review of SAMs on electrodes provides a more in-depth treatment of many topics in this article.\textsuperscript{41} Two books by Ulman survey the field of monolayers prepared by both LB and self-assembly methods.\textsuperscript{2,44} Reviews by Nuzzo cover both the use of SAMs as model surfaces and their technological applications.\textsuperscript{45,46} Other discussions of applications of SAMs have been provided by Zhong and Porter,\textsuperscript{47} Whitesides and Laibinis,\textsuperscript{37} and Wink et al.\textsuperscript{48}
deposition proceeds unimpeded. Alternatively, organic contaminants can be removed via exposure of the gold to a powerful oxidant. Popular oxidants include “piranha” solution (a 1:3 mixture of 30% hydrogen peroxide and concentrated sulfuric acid at ca. 100 °C) (Caution: this mixture reacts violently with organic material and has been known to explode when stored in closed containers!), an oxygen plasma and ozone generated by UV (ultraviolet) light. These treatments leave a surface oxide which can become trapped under a self-assembling thiol monolayer, and which can affect the properties of the SAM deleteriously. An ethanol rinse rapidly removes the gold oxide.

The other coinage metals, silver and copper, and platinum have been used as substrates for thiol SAMs. For freshly evaporated silver or copper thin films, surface oxides exist prior to SAM deposition. The self-assembly process appears to remove the oxide layer from silver but not from copper, yielding lower quality SAMs on the latter substrate. The oxide layer can be removed by an acid soak or electrochemical reduction. A recent innovation has been to form a single atomic layer of copper or silver on a gold surface by underpotential deposition (UPD) and to assemble the monolayer on the UPD layer. There is growing evidence that the bond between the sulfur and the UPD atom is stronger than the bond between the sulfur and gold atoms, resulting in a more stable SAM. It is even possible to form a UPD Cu layer after deposition of a short-chain alkanethiol SAM. Liquid mercury avoids the issues of surface crystallinity, roughness and morphology, but is easily oxidized in the presence of thiols. It is possible to prepare homogeneous and densely packed SAMs of alkanethiols on mercury via solution deposition, but not by vapor deposition.

Other substrates for thiol SAMs include nickel, indium tin-oxide, indium phosphide, and a Ti-Ba-Cu-O high-temperature superconductor.

### 2.2 Solution Adsorption

Immersion of the substrate into a homogenous solution of the self-assembling molecule at room temperature followed by rinsing is the most common approach for depositing the SAM. Usually any solvent capable of dissolving the molecule is suitable. Ethanol is the most popular solvent. The thiol concentration can be varied from micromolar levels to that of the neat thiol liquid. Very low concentrations of thiols are favored by those seeking large crystalline domains of alkanethiols via slow self-assembly, but are not a guarantee of SAM quality. There is evidence that the solvent can be trapped in the SAM and not removed by the subsequent rinsing step. Insoluble thiols can be dispersed into water with the aid of surfactants or cyclodextrins and subsequently assembled on gold. Considerable effort has been made to ascertain the time needed to form a well-organized layer. For millimolar or higher concentrations of thiols, a disordered monolayer is deposited in a few seconds. There is a much slower transformation over a period of hours to days into a highly oriented and densely packed monolayer. Scanning tunneling microscopy (STM) studies (see section 3) suggest that the gold is slightly etched during self-assembly; gold has been detected in the deposition solution. To remove kinetically trapped disordered states, the SAM is sometimes annealed by soaking it in hot deposition solution, exposing it to warm temperatures in a gaseous ambient, or subjecting the electrode to a cyclic voltammogram (CV) and repeated immersions in the deposition solution.

When two thiols are being co-deposited, the solvent, time and temperature all affect the mole fraction of each component in the SAM. The less soluble thiol is preferentially deposited. High concentrations of the thiol, long adsorption times and high temperatures encourage the SAM composition to approach equilibrium with the solution; the result is an abrupt transition of the SAM composition from one component to the other as a function of the mole ratio of the two components in solution.

### 2.3 Other Deposition Methods

Deposition of the SAM from an electrolyte with the substrate under potential control ensures that the metal is in the reduced state. A thiol SAM desorbs at very negative potentials in alkaline electrolytes (section 5.2). Consequently, a SAM can be formed in an alkaline electrolyte with dissolved alkanethiols by slowly shifting the electrode potential in the positive direction from the desorption potential. When the thiol is sufficiently volatile, SAM deposition can be performed from the vapor phase, both in a vacuum and at ambient pressures. The resulting SAMs appear to be virtually identical to those obtained by solution deposition. Majda et al. have demonstrated that monolayers very similar to those obtained by self-assembly can be obtained by spreading a mixture of alkanethiol and long-chain alkanol on a LB trough, applying compression and transferring the monolayer to a gold substrate. There are numerous approaches to producing micropatterned SAMs, but the most common is to press a patterned polysiloxane stamp inked with a thiol onto a gold substrate and then to fill in the gaps with solution deposition of a second thiol.
SELF-ASSEMBLED MONOLAYERS ON ELECTRODES

3 NONELECTROCHEMICAL CHARACTERIZATION OF SELF-ASSEMBLED MONOLAYERS

SAMs have been subjected to virtually every surface analytical method known. Among the more frequently applied tools are wetting contact angle, ellipsometry, surface plasmon resonance (SPR) spectroscopy, surface IR (infrared) spectroscopy, Raman spectroscopy, X-ray absorption spectroscopy, X-ray photoelectron spectroscopy (XPS) and Auger electron spectroscopy (AES), temperature programmed desorption (TPD), scanning electron microscopy (SEM), surface ionization mass spectroscopy (SIMS) and laser desorption mass spectroscopy (LDMS), STM and atomic force microscopy (AFM), assorted diffraction (X-ray, electron, atom) and piezoelectric methods. The following discussion is a summary of observations from all of these methods.

The mechanism of self-assembly appears to follow two stages. Initially, alkanethiols adsorb horizontally onto the metal substrate. Subsequently, the thiols lift up to form the vertically oriented layer. The thickness of the SAM is linearly related to the chain length of the thiol. On single-crystal surfaces, SAMs generally form highly crystalline lattices which are commensurate with the metal atom lattice. Chain “melting” to a more liquid-like structure has been reported in several instances, but other observations indicate only a slow increase in the degree of chain disorder as the temperature is raised. The exact binding sites and nature of bonding between the sulfur and the surface metal atoms is still not clear. The Au–S bond strength is about 40 kcal mol\(^{-1}\).\(^{118}\) On the most common metal substrate, Au(111), alkanethiols form a \((\sqrt{3} \times \sqrt{3})R30^\circ\) hexagonal lattice with an average spacing of 5.0 Å (1 Å = \(10^{-10}\) m) between alkane chains. The alkane chains are in the \textit{trans}-conformation with very few gauche defects. The average tilt of the alkane chain with respect to the surface normal is typically less than or equal to 30°. The tilt angle is controlled by the headgroup structure combined with a minimization of free volume in the alkane chain domain. A detectable C(4 × 2) unit cell of four thiols within the lattice arises from variations in the twist of the alkane chains. In highly ordered SAMs, the orientation of the terminal group can depend on the number of methylenes separating the terminal group from the thiol (the “odd–even” effect). Domains of SAMs with nanometer dimensions are separated by grain boundaries corresponding to changes in chain tilt and/or registry with the substrate surface atoms. Even when the surface of the substrate is not ordered or when a large group in the chain perturbs the packing, the exposed alkane chains often adopt a hexagonal close-packed structure. There is considerable evidence that thiols lose the hydrogen to form a surface thiolate. Disulfides cleave to form the identical thiolate. Surface metal atoms should carry a corresponding positive charge, but spectroscopic evidence for the oxidized metal layer has not been found. An X-ray diffraction study\(^{103}\) suggests that the thiolates exist as a dimer on a Au(111) surface, but there has been no other supporting evidence for this hypothesis. The degree of molecular order is very similar in SAMs prepared from thiols and from disulfides, but noticeably lower in SAMs prepared from sulfides. A controversial proposal by Zhong and Porter suggests that the C–S bond can also cleave during the self-assembly process of sulfides.\(^{104}\) STM images reveal the presence of “pits” after SAM deposition from either solution or vapor. These pits have been identified as missing single atom layers in flat terraces. The pits contain attached thiolates and are not the origin of pinholes discussed in section 5.3. Postdeposition thermal annealing causes migration of the surface gold atoms, and promotes Ostwald ripening of the “pits”. The SAMs are air stable unless they are exposed to ozone, in which case the thiolates are rapidly oxidized to sulfonates.\(^{66}\)

Most of the characterization methods indicate that mixed SAMs composed of molecules with similar chain lengths are homogeneously mixed rather than phase separated. Only in high-resolution STM images is there evidence of imperfect mixing.\(^{105,106}\) When the mixed SAM contains molecules of greatly differing chain length, phase separation into microscopic domains is detectable. The longer-chain component exhibits a greater degree of disorder since it is not stabilized by packing over the entire surface.

Slight increases in disorder of the outer part of the SAM can be detected when the SAM is brought into contact with a liquid, depending on the liquid and the terminal group of the SAM. SAMs with hydrophilic surface groups, particularly an ethylene oxide oligomer, are very resistant to adsorption of proteins from solution.\(^{57}\) Thiols with terminal acid or base groups exhibit marked changes in the ionization behavior when they are incorporated into SAMs. The ionization reaction which forms a charged species is less favored thermodynamically. Thus, alkyl carboxy groups (–COOH), which in homogeneous solution have a \(pK_a\) of about five, do not start to ionize significantly in SAMs until the pH of the contacting solution exceeds six. Complete ionization of the carboxy groups requires a much higher pH.

4 POSTDEPOSITION MODIFICATION OF SELF-ASSEMBLED MONOLAYERS

Because a diverse variety of moieties can be attached to the thiol molecule without inhibiting SAM formation,
there is an abundance of chemical transformations available to tailor the surface composition and properties. For both bond cleavage and bond formation on a SAM, both steric factors and electrostatic attraction/repulsion strongly affect the reactivity of the terminal groups. A topic not covered here is the physical transformation of SAMs via lithographic methods into patterned arrays.

Thiol exchange is accomplished by immersing the SAM in a new thiol deposition solution. The kinetics of exchange indicate the presence of two populations of molecules in the SAM, one of which is rapidly exchanged. In general, the second population is not fully replaced by the new thiol even after prolonged exposure (days) to the second deposition solution.

Ester groups near the exposed surface of a SAM can be hydrolyzed by small nucleophiles, but not by an enzyme.

Internal polymerizations of SAMs include conversion of diacetylenes to a conjugated ene–yne structure, cross-linking of a terminal vinyl group, hydrolysis and cross-linking of a trimethoxysilane, dehydration of a boronic acid to a borate glass, and electrochemical polymerization of a terminal pyrrole. The polymerized SAMs exhibit increased stability towards thermal desorption and greater resistance to exchange with solution thiols.

Numerous examples exist of reactions designed to couple a new moiety covalently to the surface of a SAM. Among the more common covalent transformations are the formation of amides and esters via acid chlorides or anhydrides or with the aid of carbodiimide coupling agents. Proteins, enzymes and other biomolecules are attached via reaction of exposed amines to SAMs with agents. Proteins, enzymes and other biomolecules are attached via reaction of exposed amines to SAMs with amino or carboxyl groups, charged planar inorganic oxide fragments and proteins, the binding is sufficiently strong that the attached layer resists removal by a water rinse. Because a bound polyelectrolyte reverses the surface charge on an ionized SAM, it is possible to build up multiple layers of polyelectrolytes with sequential immersion of the substrate in aqueous solutions of each component. Multilayers can be also constructed on SAMs via sequential deposition of a metal cation and then a difunctional molecule.

A second highly oriented layer of surfactant molecules can be deposited on the top of a SAM via LB transfer. The orientation of the outer layer depends on whether the surface is hydrophobic or hydrophilic. The importance of cell membrane phospholipid bilayers in controlling ion transport and signalling has led to a considerable effort to create analogous structures on or near solid substrates. Phospholipids spontaneously form a second layer on top of a methyl-terminated SAM from either a suspension of phospholipid vesicles, a suspension of phospholipid and detergent micelles or from the evaporation of a phospholipid solution. The resulting structure is called a hybrid bilayer. To avoid the obvious disadvantage of a bilayer with one side pinned to the substrate, suspended bilayers have been formed by creating a SAM with a remote pendant phospholipid or cholesterol and assembling the bilayer around the remote seed molecules.

5 ELECTROCHEMICAL CHARACTERIZATION OF SELF-ASSEMBLED MONOLAYERS ON ELECTRODES

5.1 Double-layer Structure and Capacitance

Electrode/electrolyte interfaces exhibit a capacitance whose magnitude reflects the distribution of ions on the solution side of the interface. The electrolyte double layer is composed of the Helmholtz layer, a layer of ions and solvent in physical contact with the electrode, and the diffuse layer, a layer of ions near the electrode whose concentration deviates from bulk concentrations. In relatively concentrated electrolytes, the capacitance of the Helmholtz layer dominates the interfacial capacitance. For most metals, typical Helmholtz capacitances range from 10–100 μF cm⁻², and are dependent on potential. When a long-chain alkanethiol self-assembles on a metal electrode, the Helmholtz layer changes from a mixture of ions and solvent with a high dielectric constant to an ion-free hydrocarbon layer with a low dielectric constant. Consequently, the interfacial capacitance is dramatically reduced and becomes virtually independent of potential.

Interfacial capacitances are often measured via the charging current in a CV. More detailed studies of capacitance behavior are obtained by AC (alternating current) impedance spectroscopy or AC voltammetry. A simple parallel-plate capacitor model predicts that the reciprocal capacitance increases linearly with the thickness of the dielectric layer. Plots of C⁻¹ versus n (number of CH₂ groups in the alkane chain) are indeed linear for the longer chain lengths. Shorter chain-length SAMs appear to be permeable to some electrolyte.
ions and exhibit greater capacitances than expected (Figure 3). Extraction of the SAM dielectric constant requires an assumption about the tilt of the alkane chains. Observed values fall in the range of 2.3–2.6. The dielectric constants are consistent with a close-packed layer of alkane chains with essentially no penetration by electrolyte solvent or ions. Mathematical models have been developed to predict the capacitances of a SAM-coated electrode when the surface charge of the SAM changes because of either an acid–base reaction or a redox reaction. Deviations from the capacitances of simple alkanethiol SAMs are useful in monitoring phenomena such as poorly packed SAMs, increased solvent and/or ion penetration and variations in the tilt of the alkane chains. Capacitance measurements are also helpful in monitoring the self-assembly process in situ and in confirming the formation of a hybrid bilayer on a SAM.

5.2 Electrochemical Stripping and Deposition of Self-assembled Monolayers

SAMs from thiols, disulfides and sulfides resist desorption over a wide potential range, but at very negative potentials and in strongly alkaline electrolytes, they are desorbed quantitatively. On single crystal surfaces or on mercury, a typical CV exhibits a rather sharp cathodic peak (or sometimes two peaks), corresponding to stripping of the thiols, and a somewhat broader anodic peak corresponding to readsoption of the thiol (Figure 4). The half reaction is thus written as Equation (1):

$$M|S(CH_2)_nX + ne^- \rightleftharpoons M^- + S(CH_2)_nX$$  (1)

where $M$ is the electrode metal. The desorption proceeds either from a few nucleation centers or nearly homogeneously across the electrode, depending on the chain length of the thiol and the applied potential.

A key observation is that the area under the desorption peak, corrected for charging current and true surface area, is independent of the chain length of the alkanethiol. The area, converted to moles of electrons per cm$^2$, is $7.8 \times 10^{-10}$ for Au(111), $7.7 \times 10^{-10}$ for Ag(111), and $9.8 \times 10^{-10}$ for Hg. The theoretical coverages of thiols (in moles cm$^{-2}$) for a ($\sqrt{3} \times \sqrt{3}$)R30° lattice are $7.7 \times 10^{-10}$ for Au(111) and $7.6 \times 10^{-10}$ for Ag(111). The data support the conclusion that $n = 1$ in Equation (1).

**Figure 3** Reciprocal capacitance of alkanethiol SAMs versus chain length $n$. The symbols represent capacitances obtained from CVs. Filled symbols indicate 10 mV s$^{-1}$ scan rate, and empty symbols indicate 100 mV s$^{-1}$ scan rate. (Reprinted with permission from Porter et al. Copyright 1987, American Chemical Society.)

**Figure 4** Electrochemical stripping and redeposition of a dodecanethiol SAM on Au(111) in 0.5 M KOH. The solid and dashed lines are the first and second scans, respectively. The dotted line is a CV of bare Au(111). (Reprinted with permission from Walczak et al. Copyright 1991, American Chemical Society.)
Schneider and Buttry argue that the correction for charging current is underestimated, so that \( n \) is smaller than 1.\(^{(144)}\) Even with this caveat, the area of the cathodic stripping peak is a useful measure of thiol coverage as a function of SAM composition\(^{(26,104)}\) and electrochemical history.\(^{(145)}\) For example, a racemic deposition mixture of an optically active thiol yields a higher coverage on mercury than do deposition solutions containing either pure enantiomer.\(^{(146)}\)

The potentials of the cathodic stripping peaks supply information about the strength of the metal–sulfur bond and the interchain interaction, the accessibility of the metal–sulfur bond to cations from the solution, and the presence of any intermediate or weakly adsorbed states.\(^{(96)}\) Gold substrates with a high density of steps connecting Au(111) terraces exhibit two stripping waves, suggesting that thiols are more strongly bonded to step sites.\(^{(32)}\) The presence of two stripping peaks for a SAM formed from an asymmetrical sulfide is part of the evidence for cleavage of the C–S bond in the sulfide.\(^{(104)}\) In some mixed SAMs, distinct stripping peaks can be assigned to each component and that component thiol selectively desorbed; both observations support the existence of phase-separated domains.\(^{(147,148)}\)

The desorbed thiols tend to remain near the electrode and are readily readsobered when the electrode potential is shifted to a more positive value. It is possible to create partial monolayers by controlling the electrode potential prior to and during emersion.\(^{(95)}\)

### 5.3 Blocking Behavior

Alkanethiol SAMs suppress faradaic processes such as electrode oxidation and the exchange of electrons between the electrode and solution redox couples. This blocking property is attributed to the densely packed structure of the hydrocarbon chains which impede the approach of solution ions and molecules to the electrode surface. Possible applications of blocking SAMs can be found in the areas of corrosion prevention, nanoscale lithography and selective electrodes. However, closer examination of SAM-coated electrodes reveals the presence of pinholes (bare metal sites) and other defects, which permit a close approach of solution species. It is important to understand the nature, size and distribution of the pinholes and other defects before the applications mentioned above are achievable.

Of all the methods for probing SAM structures, voltammetry is the most sensitive tool for detection of pinholes and defects in a SAM. The extraordinary sensitivity arises from the ability to detect currents corresponding to oxidation or reduction of a fraction of a monolayer, and from the high rates of mass transfer of redox couples to small “hot spots” on an otherwise blocked electrode. For the subsequent discussion, we define the area fraction of pinholes as \( 1 – \Theta \), where \( \Theta \) is the fractional coverage relative to a complete monolayer. Gold oxidation is suppressed by the thiol SAM, except at pinholes. Consequently, a measurement of \( 1 – \Theta \) can be obtained from the charge needed to reduce the oxide.\(^{(7)}\) Cyclic voltammetry of solution redox couples at electrodes with imperfect SAMs exhibits current peaks or small current plateaus at low overpotentials (near the formal potential \( E^0 \)) (Figure 5). These current peaks or plateaus greatly exceed the extremely small tunneling currents found on electrodes with perfect SAMs (section 6.5). The degree of attenuation of the current by the SAM at low overpotentials relative to the currents at a bare electrode is often used as a qualitative assessment of pinholes and defects in the SAM.

Quantitative measurements of \( 1 – \Theta \) require a model. One model treats the pinholes as an array of micro-electrodes in an insulating plane. Given the somewhat

![Figure 5](image-url)
unrealistic assumptions of uniform size and uniform spacing for the microelectrodes, CVs can be fitted with calculated voltammograms (the symbols in Figure 5) to obtain the pinhole parameters (the pinhole radius $R_p$, the radius of the blocked area around the pinhole $R_b$, and $1 - \Theta$). In alternating current impedance spectroscopy (ACIS), the electrode is biased at the Nernst potential (at or close to $E^0$) in an electrolyte containing both the oxidized and the reduced forms of a redox couple and the impedance of the system is measured as a function of frequency. The same model is used to interpret the data. Typical values obtained are $10^{-2}$ to $10^{-4}$ for $1 - \Theta$ and micrometer to submicrometer dimensions for $R_p$. Deviations between the impedance behavior predicted by the model and the observed impedance behavior suggest that the pinholes are not uniformly distributed in size and in spacing.

Alternatives to the electrochemical approach for pinhole detection and mapping include deposition of metals or etching the substrate metal in the presence of the SAM and then scanning the surface with STM, AFM or SEM. These experiments suggest that the pinholes are of atomic dimensions, subnanometer rather than micrometers. Scanning electrochemical microscopy (SECM), a method which maps electroactive “hot spots” on an electrode, indicates that pinholes are less than 0.5 µm in diameter. It is likely that the apparent submicrometers to micrometers dimensions of pinholes obtained by voltammetric methods arise from areas with a high density of subnanometer pinholes.

Unfortunately, no procedure has been developed which reliably yields pinhole-free SAMs. A survey of the literature indicates that the least defective SAMs are obtained most consistently on freshly deposited thin films of metal or on mercury. For bulk solid metal electrodes, surfaces should be annealed, cleaned of organic contaminants, and etched to expose fresh metal and to remove inorganic oxides, a potential source of pinholes. In general, flexible chains yield better blocking properties than rigid ones. Postdeposition procedures that reduce the defectiveness of a SAM include electrochemical polymerization of phenol and polymerization of a diacetylene SAM. However, polymerization of a terminal vinyl group has the opposite effect.

Nonaqueous electrolytes tend to increase the permeability of SAMs, presumably because of increased solvent interactions with the pendant chains. Some redox couples (e.g. ferrocenemethanol, benzoquinone) are not blocked by even pinhole-free SAMs in aqueous electrolytes by virtue of their hydrophobicity. Electrostatic attraction or repulsion between surface moieties on the SAM and solution redox couples have a powerful effect on the blocking behavior of SAMs. These last two observations form the basis of the creation of selective electrodes (section 6.2).

5.4 Attached Redox Centers

SAMs afford a highly flexible and convenient method for attaching redox centers to electrodes. The coverage of the redox center can be varied without lowering the packing density of the SAM, thereby controlling the lateral spacing between redox centers (Figure 6). The spacing between the electrode and the redox center is determined by the chain length; close packing prevents motion of the redox center towards the electrode. It is possible to control the local environment near the redox center by either partially burying the redox center in the hydrocarbon domain, or by varying the terminal group of diluent thiols. In particular, proteins are less likely to suffer denaturing structural changes when they are attached to a hydrophilic SAM surface compared to their interaction with a bare metal. The redox centers serve as a sensitive and nondestructive probe of the structure of SAMs (especially in mixed SAMs), their dynamics (thiol exchange) and their reactivity (surface attachment and hydrolysis reactions). For electron-transfer kinetic studies, electroactive SAMs are much less sensitive to pinholes and other defects than the blocking SAMs. The redox centers provide a means of catalyzing electron transfer to kinetically slow species (see section 6.4). A wide range of redox centers have been incorporated into SAMs, including ferrocenes, ruthenium and osmium complexes, viologens, porphyrins, heme proteins, (hydro)quinones, azobenzenes and fullerences. Several strategies exist for the formation of multilayers of redox centers.

There are two main approaches to creating an electroactive SAM. The redox center may be prepared with a pendant thiol prior to deposition, or it may be coupled to the SAM via electrostatic binding, or amide or ester bond formation after deposition. In either approach, there are a
The anodic and cathodic peak potentials are identical (\(\Delta E_p = 0\)) and are equal to \(E^0\). The peak half-width \(\Delta E_{\text{fwhm}}\) is 3.53RT/nF, or 90.60 nV at 25 °C.

Departures from the ideal CV diagnostics are common and reveal molecular detail about the redox center and/or the SAM. A nonzero peak splitting indicates possible intermolecular interactions between the redox centers or a change in SAM structure with respect to the oxidation state of the redox centers (e.g. precipitation of the redox center with a counter ion). \(\Delta E_{\text{fwhm}}\) can be either greater or smaller than the theoretical value. Large values of \(\Delta E_{\text{fwhm}}\) may be caused by a spread of formal potentials (possibly indicating a disorganized SAM structure with a range of local environments about the redox centers), intermolecular interactions between redox centers or double-layer effects. In the latter case, the change in charge density of the SAM surface causes a variation in the local electrostatic potential.\(^{139,159}\) The distortion of the CV is reduced when the coverage of redox centers is low and/or ion-pairing reduces the change in charge density with oxidation state. Sharp CVs with small \(\Delta E_{\text{fwhm}}\) values are obtained if the redox centers tend to form a solid-like phase; this occurs only in the most densely packed electroactive SAMs.\(^{156}\)

The formal potential is also informative. Generally, attached redox couples on the external surface of the SAM exhibit \(E^0\) values within 100 mV of the \(E^0\) of a solution analog, suggesting that the local solvation and dielectric constant are similar to that found at a bare electrode. For high coverages of redox centers with at least one charged oxidation state, \(E^0\) shifts at a Nernstian rate (60/n mV) with each decade change in concentration of the oppositely charged counter ion in the electrolyte.\(^{157}\) This shift is due to the migration of the counter ion in or out of the SAM to provide charge compensation during the oxidation or reduction. The ion migration is also detected as mass changes for SAMs on quartz crystal microbalances (QCMs).\(^{158,159}\) Formal potentials shift markedly as the redox center becomes progressively more buried in the hydrocarbon domain of the SAM.\(^{160}\) The direction of the shift is consistent with the destabilization of the more highly charged oxidation state. Ion pairing is invoked to explain shifts in \(E^0\) with respect to the identity of the electrolyte counter ions.\(^{160}\)

A brief overview of the behavior of some of the more common redox centers will be given; see Table 1 for characteristic parameters.

Ferrocene derivatives constitute the largest class of attached redox centers. Maximum coverages in SAMs are consistent with a close-packed layer of ferrocenes. The formal potential can be shifted over a 0.5 V range, depending on the presence of electron-donating or

$^a$ Coverage $\times 10^{-10}$ mol cm$^{-2}$.

electron-withdrawing substituents. Thiol exchange reactions in SAMs have been monitored by ferrocene thiols with distinguishable formal potentials. The reduced ferrocene is chemically stable, but the oxidized ferrocenium is subject to nucleophilic attack by hydroxide with concomitant loss of coverage, so acidic electrolytes are preferred. The peak shape of 100% ferrocene thiol SAMs is usually distorted by double-layer effects or the formation of a solid-like phase. However, carefully prepared mixed SAMs containing a low density of ferrocene thiols exhibit ideal CV shapes, suggesting that the redox centers reside on the external surface of the SAM. (161)

The pyRu(NH$_3$)$_5$$^{2+/3+}$ (py = pyridine) redox center has been thoroughly studied. (92) The reduced coverage relative to that of ferrocene SAMs reflects the electrostatic repulsion between cationic redox centers and the need to incorporate counter ions in the SAM. Like ferrocene, the Ru redox centers are unstable in the oxidized state in alkaline electrolytes. Unlike the ferrocenes, nearly ideal CV peak shapes are obtained at all coverages in aqueous electrolytes. In nonaqueous electrolytes, the CV peak shapes become broader and more distorted; the change is reversible upon reimmersion in aqueous electrolytes. (162)

CVs of attached metalloporphyrins are generally poorly defined unless the porphyrin ring is incorporated into a protein or protein fragment. Cytochrome c has been studied extensively. This protein can be attached via amide formation or by electrostatic binding. (163) It is believed that the electrostatic binding orients the heme-containing cleft towards the SAM surface. The observation that $\Delta E_{\text{fwhm}}$ is consistently larger than 100 mV has been interpreted in terms of a Gaussian spread of formal potentials, suggesting a heterogeneity in the orientation of the proteins. (164, 165) Microperoxidase-11 is an oligopeptide containing a heme group and several carboxy groups which are usually attached to a cystamine SAM. (166) This protein fragment is a useful electrocatalyst. (167)

Viologens (4,4'-bipyridiniums) exhibit two distinct one-electron waves at negative potentials. In SAMs, the viologens yield high coverages and nonideal CV shapes due in part to a tendency of the radical cation to dimerize and the hydrophobicity of the two reduction products. The CVs are sensitive to the identity and concentration of the counter ions. (159) Quinones and azobenzenes generally exhibit high and stable coverages, very slow electron-transfer kinetics and very broad peaks, due in part to the dense packing achieved by these neutral organic redox centers. The formal potentials show the expected Nernstian shift with pH for a 2H$^+$/2e$^-$ half reaction. (168, 169) In very densely packed SAMs, azobenzenes are electrochemically silent, presumably because of strong inhibition of ion ingress and the significant structural change during reduction. (170)

6 ELECTROCHEMICAL APPLICATIONS OF SELF-ASSEMBLED MONOLAYERS ON ELECTRODES

The following discussion focuses on applications of SAMs for the enhancement of signal-to-noise in voltammetry, the development of selective electrodes, electrocatalysis, the study of electron-transfer kinetics over long distances and at large driving forces and the control of corrosion and adhesion at electrodes.

6.1 Microarray Electrodes

Microarray electrodes offer advantages for both analytical and kinetic studies because the electrode capacitance is greatly reduced and mass transfer is greatly enhanced relative to surface faradaic processes. The resulting improved signal-to-noise on a SAM-coated electrode has been demonstrated for the voltammetry of Ru(bpy)$_3$$^{2+/3+}$ (bpy = 2,2'-bipyridine) in the presence of gold oxidation and oxide reduction. (171) However, for practical applications, it is necessary to control the density and size of the pinholes in the SAM. Mixed SAMs composed of a long-chain alkane thiol and a short thiol (3-mercaptopropionic acid, 148) 4-aminothiophenol (172)) form phase-separated
domains of the short thiol with dimensions on the order of 10^9 nm^2 under the right conditions. Reproducible microarray behavior has been obtained for mixed SAMs of hexadecanethiol and 4-hydroxythiophenol.\textsuperscript{153,173} It is probable that the “microelectrodes” are phase-separated domains of 4-hydroxythiophenol. At low microelectrode density, the mixed SAM shows a preferential response to neutral redox species over charged ones, suggesting the presence of adsorption or permselectivity through the hydrophobic SAM. A similar microarray electrode has been fabricated by LB deposition of a mixture of the hydrophobic SAM. A similar microarray electrode has been fabricated by LB deposition of a mixture of octadecanethiol plus octadecanol containing a small percentage of ubiquinone.\textsuperscript{102,174} In this system, the density of “molecular gates” is readily controlled. At ubiquinone coverages less than 10^{-12} mol cm^{-2}, the current per ubiquinone becomes independent of the ubiquinone coverage. This is evidence for electron transfer at isolated “molecular gates”. Like the preceding system, the microarray electrode exhibits greater response for hydrophobic redox couples than for hydrophilic ones.

6.2 Selective Permeation

For SAMs that are less than perfectly blocking, selectivity arises from the inherent affinity of hydrophobic molecules for the alkane domain. This property has been applied in the development of a liquid chromatography (LC) electrochemical detector which is selective for neutral organic analytes over ionic compounds.\textsuperscript{175} Even more dramatic are electrostatic effects. The current is greatly enhanced at an ionic SAM for redox species of the opposite charge and strongly suppressed for a redox species of the same charge.\textsuperscript{176–178} For example, cationic dopamine can be detected in the presence of 100-fold higher concentration of anionic ascorbic acid at a gold electrode coated with w-mercaptoalkanoic acid.\textsuperscript{179} Interestingly, a highly charged and hydrophilic SAM containing w-mercaptoctanesulfonic acid strongly blocks organic redox couples, regardless of their charge.\textsuperscript{180}

By extension, a bilayer of molecules on or near the electrode surface should provide even greater selectivity for analytes if ion transport agents are incorporated into the bilayer.\textsuperscript{133,181} A phospholipid bilayer can be formed near but not on an electrode coated with a SAM whose constituent molecules possess a long hydrophilic body and a hydrophobic phytanyl tail.\textsuperscript{135} The hydrophobic tails serve as nucleation sites for the spontaneous assembly of a bilayer. When valinomycin is incorporated into the bilayer, the conductivity of the assembly exhibits a marked increase in the presence of K^+, and a smaller response in the presence of other cations.

A hybrid bilayer containing an alkanethiol and a phospholipid is strongly blocking towards ferricyanide until melittin is added to the solution.\textsuperscript{130} Melittin, a cationic oligopeptide isolated from bee venom, is believed to aggregate in bilayers and to create pores that are much larger than most ions. Thus, selectivity should be minimal, except possibly for electrostatic effects due to the positive charge of melittin.

6.3 Preconcentration and Selective Binding

Preconcentration implies that the analyte partitions preferentially into the SAM or to its external surface, so that the analytical signal is enhanced. Preconcentration without designed binding sites depends on hydrophobic/hydrophilic or electrostatic forces. Thus, SAMs with a terminal COOH group preconcentrate Cd^{2+}, while SAMs with a terminal pyridinium bind chromate, allowing detection of these ions down to 10^{-10} M with cathodic stripping voltammetry.\textsuperscript{182,183} Cationic surfactants are quantified by the current obtained for the reduction of ferricyanide at an octadecanethiol-coated electrode; adsorption of the cationic surfactant on the SAM enhances the concentration of ferricyanide and hence the current.\textsuperscript{184}

Designed binding sites in the SAM can greatly enhance the selectivity of the electrode (Table 2). Cyclodextrins, either with a pendant thiol or attached to an existing SAM, bind electroactive analytes like ferrocene\textsuperscript{185} or quinone.\textsuperscript{186} Nonelectroactive trans-azo dyes, which also bind to cyclodextrins, are detected either by competitive inhibition\textsuperscript{187} or by attachment of an electroactive viologen to the dye.\textsuperscript{188} The formal potential of a cyclic bis(bipyridinium) molecule in a SAM shifts in the negative direction in the presence of indole or catechol.\textsuperscript{189} A bis(acetylacetone)sulfide forms SAMs that bind Cu^{2+}, Pb^{2+} and Zn^{2+} selectively in the presence of Fe^{2+} or Fe^{3+}.\textsuperscript{190–192} The first three ions readily form four-coordinate complexes, while iron cations prefers a six-coordinate geometry. The bound Cu^{2+} or Pb^{2+} act as nucleation sites for the electrodeposition of bulk copper or lead. Consequently, direct measurements are possible for Cu down to 10^{-7} M and Pb down to 10^{-5} M, and an indirect measurement of Zn can be made down to 10^{-9} M. A mixed SAM containing octadecanethiol and a flat oriented steroid partially blocks ferricyanide.

reduction. The reduction current is greatly attenuated when cyclic polyols with equatorial OH groups are present in the solution. The polyols are thought to form ice-like structures in the cavities defined by the steroid molecules.

Incorporation of enzymes into SAM structures affords highly selective electrodes. Direct electron transfer between the enzyme and the electrode is relatively rare; most biosensors use a freely diffusing or attached redox couple to catalyze electron transfer to the enzyme (see section 6.4). Examples of the former approach include electrodes selective for the reduction of fumarate, the oxidation of hydrogen peroxide, and the oxidation of lactate.

A particularly elegant approach to a biosensor is based on a suspended bilayer near a gold surface (Figure 8). The bilayer contains gramicidin fragments in the inner layer which are tethered to the gold surface, and hence are fixed. Gramicidin fragments in the outer layer contain a biotin tag which is connected via streptavidin to a biotin-tagged antibody fragment. In the absence of the analyte, the outer-layer gramicidin molecules diffuse laterally and intermittently form ionically conducting dimers with the inner layer gramicidin; the conductivity of the bilayer, measured by AC impedance, is relatively high. In the presence of the analyte, the outer-layer gramicidins become locked to fixed antibody fragments and thus can no longer form conducting dimers. The signal is the rate of decrease in the conductance of the bilayer. This sensor is potentially competitive with enzyme-linked immunosorbent assay in terms of flexibility, selectivity and sensitivity, and does not require the washings or reagent additions of the latter method.

6.4 Electrocatalysis

In electrocatalysis (also known as mediated electron transfer), a redox couple, either attached or freely diffusing, transfers electrons between the electrode and target redox couple. The target redox couple is thermodynamically capable of being oxidized or reduced at the electrode, but the electron-transfer kinetics are extremely slow. Kinetically slow systems include multielectron redox centers and enzymes whose redox centers are inaccessible to the electrode. Because electron transfer between the electrocatalyst and the target molecule is usually thermodynamically downhill, a characteristic feature of voltammograms is catalytic current in one direction only (anodic or cathodic).

SAMs serve two roles in electrocatalysis. First, they provide a flexible means of anchoring the electrocatalyst and/or the enzyme. Second, SAMs block access of the target redox couple to the electrode, a useful feature for fundamental studies. For example, SAMs with pendant ferrocenes block reduction of Fe$^{3+}$ at the $E^0$ of the Fe$^{2+}$/Fe$^{3+}$ redox couple, but catalyze the reduction of Fe$^{3+}$ at potentials where the attached ferriceniums are reduced. It is possible to measure the rate constant for electron exchange between the catalyst and the target. A SAM containing a remarkable quinone that exhibits photoisomerization between an electroactive and a nonelectroactive form is the basis of a light-switchable electrocatalytic electrode.
Numerous examples exist of electrocatalysis of multi-electron redox systems. The two-electron reduction of O$_2$ to H$_2$O$_2$ is catalyzed by attached cobalt porphyrins,\textsuperscript{199,200} while the four-electron reduction to water is catalyzed by an attached tetrone (diquinone), albeit at potentials well negative of the thermodynamic potential.\textsuperscript{201} NADH oxidation is catalyzed by attached catechols,\textsuperscript{202,205} NO reduction is catalyzed by Cr(terpyridine)$_2$$^{3+}$,\textsuperscript{204} H$_2$O$_2$ reduction is catalyzed by iron porphyrin or heme protein,\textsuperscript{166,167} and both ascorbate and hydrazine oxidation are catalyzed by immobilized ferricyanide (possibly as a Prussian blue-like complex).\textsuperscript{205}

Likewise, enzymes have been immobilized on SAMs and their catalytic reaction driven by electrocatalysis. If the electrocatalyst is freely diffusing in the electrolyte, then the SAM must be made permeable to the electrocatalyst. A mixed SAM containing octadecanethiol and dibenzyl disulfide is the base for a hybrid bilayer containing pyruvate oxidase; the benzylthiolate canethiol and dibenzyldisulfide is the base for a hybrid electrolyte, then the SAM must be made permeable to the electrocatalyst ferrocenemethanol to the electrode.\textsuperscript{206} Alternately, the electrocatalyst and the enzyme are both attached to the SAM. Glucose oxidase can be attached to a mixed SAM of 2-aminoethanethiol and a long chain ferrocenethiol.\textsuperscript{207} More complex structures containing multiple layers of enzymes and electron catalysts have been constructed with the purpose of improving the sensitivity of the sensor or making the sensor light-switchable; in each case, the base coat is a SAM of cystamine.\textsuperscript{120,121,208–210}

6.5 Long-range Electron Transfer

The close-packed structure of the alkanethiol SAM provides a useful spacer for anchoring redox centers at fixed and controllable distances from the electrode surface (Figure 6). Mixed SAMs allow adequate spacing between redox centers without loss of packing density. The redox centers can also be freely diffusing if the SAM is completely free of pinholes and other defects (section 5.3), but that condition is difficult to prove.\textsuperscript{5,211,213} The alkane chain is an insulator, and as a consequence, electron transfer must proceed by a tunneling mechanism. The rate of electron transfer is diminished to the point that the rate constants can easily be measured over a wide range of overpotentials ($\eta = E - E^\circ$). Both of these facts have been widely exploited by researchers interested in long-range electron transfer and in fundamental theories of electron transfer. The prevailing theory is the Marcus DOS (density of states) model.\textsuperscript{213,214} This model focuses on the overlap of donor and acceptor energy levels in the electrode and in the redox center. It includes an important parameter in Marcus theory called the reorganization energy ($\lambda$), which is the energy needed to change the redox-center structure and its solvation sphere between the equilibrium states for the two oxidation states.

A number of electrochemical methods provide access to the rate of electron transfer: cyclic voltammetry,\textsuperscript{215} ACIS,\textsuperscript{216} square-wave voltammetry,\textsuperscript{217} and chronoamperometry.\textsuperscript{213,218} These electrochemical methods are useful for rate constants in the range $10^{-2}$ to $10^5$ s$^{-1}$. Measurements of rate constants outside this range require spectroscopic\textsuperscript{219} or temperature-jump methods.\textsuperscript{220}

Three types of experimental results are of interest. A plot of ln $k^0$ ($k^0$ is the standard rate constant at $n = 0$) versus the number of repeating units in the tether (i.e. the number of CH$_2$ groups in the alkane chain) is usually linear, indicating that tunneling rates decay exponentially with distance (Figure 9).\textsuperscript{213,220–224} The slope of the plot yields the tunneling parameter $\beta$. For a single monolayer, a plot of ln $k$ versus $\eta$ (Tafel plot) is nearly linear, but with some curvature (Figure 10). Fitting the curvature to the Marcus DOS model yields $\lambda$, the reorganization energy. The reorganization energy can also be obtained from a plot of ln $k^0$ versus $T^{-1}$ (Arrhenius plot).

Detailed experimental studies have been performed on SAMs with attached ferrocenes, pyRu(NH$_3$)$_5^+$, and cytochrome c.\textsuperscript{1} For alkanethiols on gold, plots of ln $k^0$ versus the number of CH$_2$ groups are linear. Values for the tunneling parameter $\beta$ are 1.0–1.1 per CH$_2$. The same $\beta$ is obtained for blocking SAMs and various redox couples in solution.\textsuperscript{221} Assuming a 30° tilt for an all-trans alkyl chain, $\beta$ is 1.0–1.1 Å$^{-1}$. Theoretical calculations are in agreement with this value.\textsuperscript{225,226} The tunneling mechanism invokes electronic coupling of the metal and redox-center orbitals via the highest filled and lowest unoccupied molecular orbitals of the connecting alkane chain. From this model, a substantial

![Figure 9](image-url)
lowering of \( \beta \) is expected if a fully conjugated spacer is used in the SAM. As predicted, a SAM composed of repeating phenyl–alkynyl spacer units yields a \( \beta \) of 0.6 Å. Insertion of a heteroatom, a double bond or a triple bond into the repeating CH₂ spacer unit in an alkane chain reduces the electronic coupling. Several experiments suggest that electronic coupling through alkane chains not attached to or in contact with the redox center can contribute significantly to the total electronic coupling.

In general, reorganization energies obtained from Tafel plots and Arrhenius plots are in agreement. The \( \lambda \) values are also in surprisingly good agreement with a simple theoretical equation based on the energy of a charged sphere in a dielectric continuum. Table 3 lists selected \( \lambda \) values obtained in aqueous electrolytes.

### 6.6 Corrosion Control

The most popular metal substrate, gold, is hardly in need of corrosion protection in everyday use. However, protection from chemical etchants is a useful property in the preparation of patterned gold arrays. Two etchants for gold that are effectively blocked by long-chain alkanethiol SAMs are an oxygen-saturated alkaline cyanide bath and a solution of ferricyanide combined with thiocyanate or thiosulfate. Various gold microelectrode geometries have been fabricated by this means.

Corrosion protection of copper by SAMs has received more attention, principally by Aramaki et al. An alkanethiol SAM affords modest protection against corrosion in aqueous electrolytes. Better corrosion protection is obtained by first depositing a SAM of 11-hydroxyundecanethiol, and then reacting the exposed OH groups with octadecyltrichlorosilane. The 5-nm bilayer inhibits both O₂ reduction and copper oxidation in solution and provides excellent protection against indoor atmospheric corrosion for nearly a year. An XPS study of copper corrosion shows that both the copper and the sulfur are oxidized and that the rate of corrosion in air decreases dramatically with a small increase in SAM thickness. Pit corrosion is clearly evident when a SAM-coated Cu(100) surface is exposed to dilute HCl solution, suggesting that chemical attack occurs at defects in the SAM.

### 6.7 Adhesion Control

Several organic compounds (aniline, pyrrole, thiophene) undergo polymerization reactions when oxidized to form conducting polymers. When the monomers are oxidized at an electrode, the polymers precipitate onto the electrode to form a coating. The conducting polymer coatings have potential applications in the areas of electrochromism, charge storage and organic semiconductors. It is desirable to create smooth and adherent coatings on the electrodes.

SAMs containing the monomer greatly improve the adhesion, smoothness and density of the conducting polymer coatings. The SAM appears to encourage the formation of many nucleation sites for growth of the polymer. Thus, a poly(aniline) film deposited on a gold electrode coated with a SAM of 11-aminothiophenol and octadecanethiol, poly(aniline) is selectively deposited on the aminothiophenol domains. A mechanism for initiation and growth of poly(aniline) on the SAM has been
proposed.\textsuperscript{(246)} SAMs of \(w\)-(N-pyrrole)alkanethiol greatly improve the adhesion\textsuperscript{(247,248)} and smoothness of deposited poly(pyrrole).\textsuperscript{(249)} A linear mass change versus charge obtained on a QCM indicates that the poly(pyrrole) is depositing layer by layer, rather than by growth of clumps.\textsuperscript{(250)}

SELF-ASSEMBLED MONOLAYERS ON ELECTRODES

I. Turyan, D. Mandler, ‘Self-assembled Monolayers in Electroanalytical Chemistry: Application of w-Mercapto carboxylic Acid Monolayers for Electro-

The study of processes that transpire at heterogeneous interfaces is an exceedingly difficult proposition. No single experimental technique can ever hope to unravel all the nuances of heterogeneous reactions; hence, in surface science, the use of multiple complementary methods is not uncommon. Ultrahigh vacuum electrochemistry (UHV/EC) is a term ascribed to the approach that rests upon the integration of classical electrochemical methods with surface-sensitive analytical techniques; this strategy parallels that successfully implemented in the study of gas–solid heterogeneous catalysis. The unique surface sensitivity of the techniques adopted emanates from the use of particles (e.g. ions or electrons) that serve to interrogate the outermost layer(s) of the electrode. This surface sensitivity is tempered by the requirement that the analysis be performed in an environment (outside the electrochemical cell) that does not impede the mean-free paths of the probe particles. Since its inception in the early 1970s, more than a thousand UHV/EC-based studies have been published; most of the work involved polycrystalline materials and focused on the elemental composition at the electrode surface. While its importance in the study of polycrystalline surfaces cannot be trivialized, the greater value of UHV/EC appears to be in its ability to help resolve fundamental issues that intertwine interfacial structure and composition with electrochemical reactivity. It is in this context that the present review is written.

A complete mechanism of an electrochemical reaction must incorporate all the physical and chemical interactions that arise between an electrified surface and its environment. The extent of such interactions depends upon several factors such as solvent, supporting electrolyte, electrode potential, reactant concentration, electrode material and surface crystallographic orientation. The traditional approach is based upon a thermodynamic treatment of the interface and its response to external perturbations. Interpretation of the results relies on phenomenological models of the interface. Although a thermodynamic treatment cannot be ignored, the need for an atomic-level view has long been realized. One approach(1–12) towards the establishment of an atomic-level description parallels that successfully implemented in the study of gas–solid heterogeneous catalysis; it rests upon the integration of classical electrochemical methods with surface-sensitive analytical techniques. The analytical methods that exhibit surface sensitivity are based upon the mass-selection and/or energy-discrimination of electrons, ions, atoms or molecules scattered from solid surfaces. These particles have shallow escape depths; hence the information they bear is characteristic of the near-surface layers. Their short mean-free paths, however, necessitate a high vacuum (<10^-6 torr) environment. The application of such surface techniques to electrochemistry requires that the analysis be performed outside the electrochemical cell. The possibility of structural and compositional changes that accompany the removal of the electrode from solution is
the major concern in UHV/EC studies. Although a myriad of surface analytical techniques is currently available, those actually employed in UHV/EC have been limited to low-energy electron diffraction (LEED), Auger electron spectroscopy (AES), X-ray photoelectron spectroscopy (XPS), high-resolution electron energy loss spectroscopy (HREELS), reflection high-energy electron diffraction (RHEED), work-function changes, and thermal desorption mass spectrometry (TDMS).

While most vacuum-based analytical methods do not require single-crystal surfaces, the use of uniform (monocrystalline) surfaces is a necessary aspect for fundamental studies. The low-index crystallographic faces [(100), (110) and (111)] have been widely used because of their low free energies, high symmetries, and relative stabilities. In addition, it may be possible to reconstruct the overall behavior of polycrystalline electrodes from the individual properties of the low-index planes. (1-4) A handful of procedures for the preparation and preservation of well-defined single-crystal surfaces have been described. (5-8) The verification or identification of initial, intermediate, and final interfacial structures and compositions is an essential ingredient in electrochemical surface science.

1 SURFACE CHARACTERIZATION TECHNIQUES

1.1 Surface Spectroscopy with Low-energy Electrons

The main difficulty in surface analysis lies in the exceedingly low population of atoms at the interface (10^{15} atoms cm^{-2}) relative to that in the bulk (10^{23} atoms cm^{-3}). Experiments intended to examine the physical and chemical properties of surfaces must employ methods that interact only with the interfacial layers; the majority of such techniques take advantage of the surface sensitivity of low-energy electrons. The surface sensitivity arises because the mean-free-path of an electron through a solid is dependent upon its kinetic energy. As shown in the “universal curve” reproduced in Figure 1, the electron mean-free-path falls to a minimum (0.4 to 2 nm) when the kinetic energy is between 10 and 500 eV. That is, information derived from experimental techniques based upon low-energy-electron incidence onto and/or emergence from surfaces will exclusively be from the topmost surface layers.

A solid surface subjected to a beam of electrons of incident (primary) energy E_p gives rise to the appearance of backscattered and emitted electrons; a plot of the number of electrons N(E)/E as a function of energy E of these electrons is shown in Figure 2. (9-15) This spectrum can be divided into four regions according to the origin of the scattered electrons: (i) true secondary electrons, created as a result of inelastic interactions between the incident and bound electrons, give rise to the prominent broad band at the lower end of the spectrum; (ii) Auger electrons emitted and primary electrons scattered due to interactions with electronic states in the solid account for the small peaks in the medium-energy range of the spectrum; (iii) primary electrons scattered upon interactions with the vibrational states of the surface yield peaks close to the elastic peak; (iv) primary electrons scattered

![Image of Figure 1](image-url)
elastically, which comprise only a few percent of the total incident electrons, appear at \( E_p \). The spectral regions (ii) to (iv) have been exploited in modern surface analysis.

### 1.2 Low-energy Electron Diffraction

In this method,\(^{(9-15)}\) the surface is irradiated with a monoenergetic beam of electrons and the elastically backscattered electrons are collected onto a phosphor screen. The virtue of LEED as a surface structural technique is a result of the low kinetic energies used (50 to 500 eV): (i) the electron mean free path is at a minimum; (ii) the de Broglie wavelengths, \( \lambda_e \approx (150/E_e)^{1/2} \) (where \( E_e \) is in electronvolts and \( \lambda_e \) is in angstroms) correspond to crystal lattice dimensions; and (iii) electron backscattering is strong which minimizes incident electron fluxes at, and subsequent scattering from, nonsurface layers. In LEED, the presence (or absence) of diffraction patterns on the fluorescent screen is a consequence of the order (or disorder) of the atomic arrangements at the surface.

The locations of the diffraction spots define the reciprocal lattice of the real surface. The real-space surface structure can be reconstructed from the reciprocal lattice vectors.\(^{(9-15)}\) The coherence width of electron beam sources in LEED is typically 10 nm. That is, sharp diffraction features appear only if well-ordered domains are at least 10 nm \( \times 10 \) nm in size; diffraction from smaller domains leads to beam broadening. The analysis of LEED data based solely upon the geometry of the diffraction spots provides information on the periodicity of the electron scatterers on the surface. In some favorable instances, other information such as adsorbate coverages or point group symmetries can also be inferred. However, the actual location of the atoms within the surface lattice cannot be determined without an analysis of the intensities of the diffracted beams. Surface crystallography by LEED relies upon a comparison of the measured diffraction intensities with those calculated for model structures. LEED simulations are difficult because of multiple electron scattering.\(^{(9-15)}\)

Two schemes are employed for the notation of interfacial adlattice structures. The matrix notation, which is applicable to any system, is based upon the relationship between the real-space lattice vectors of the adsorbate mesh (two-dimensional lattice) and the substrate mesh. For example, if the adsorbate unit cell vectors \( \mathbf{a}' \) and \( \mathbf{b}' \) are related to those of the substrate mesh, \( \mathbf{a} \) and \( \mathbf{b} \), according to Equations (1) and (2):

\[
\mathbf{a}' = m_{11} \mathbf{a} + m_{12} \mathbf{b} \tag{1}
\]

\[
\mathbf{b}' = m_{21} \mathbf{a} + m_{22} \mathbf{b} \tag{2}
\]

Then the matrix \( \mathbf{M} \) defined by the coefficients \( m_{ij} \), \( \mathbf{M} = \begin{pmatrix} m_{11} & m_{12} \\ m_{21} & m_{22} \end{pmatrix} \), denotes the real-space surface structure.

The other method, known as the Wood notation,\(^{(16)}\) is more widely used but is applicable only if the angle between \( \mathbf{a}' \) and \( \mathbf{b}' \) is the same as that between \( \mathbf{a} \) and \( \mathbf{b} \). The adlattice structure is labeled using the general form \( (n \times m)R_\phi^c \) or \( c(n \times m)R_\phi^o \), where \( c \) designates a centered unit cell, \( R_\phi^o \) the angle of rotation of the adsorbate unit cell relative to the substrate unit mesh, and \( n \) and \( m \) are scale factors relating the adsorbate and substrate unit cell vectors \( |\mathbf{a}'| = n|\mathbf{a}| \) and \( |\mathbf{b}'| = m|\mathbf{b}| \).

A schematic diagram of a typical LEED instrument is shown in Figure 3.\(^{(17)}\) The LEED "optics" consists of a phosphor-coated hemispherical screen at the center of which is a normal-incidence, electrostatically focused electron gun. In front are three concentric grids; the outer grid is held at ground potential, while the inner two are maintained at a voltage just below that of the electron gun in order to reject inelastically backscattered electrons. The elastically diffracted electrons which pass through the suppressor grids are accelerated onto the fluorescent screen by a 5-kV potential applied to the screen. For quantitative intensity measurements, additional provisions (e.g. Faraday cup, spot photometer, or digital camera) will be necessary.

A typical LEED pattern, that for an iodine-coated Pd(111) surface, is shown in Figure 4 along with the suggested real-space adlattice structure, Pd(111) \( - (\sqrt{3} \times \sqrt{3})R30^\circ - I \).

### 1.3 Reflection High-energy Electron Diffraction

RHEED\(^{(2,12-15)}\) represents an alternative to LEED. The principal difference between the two techniques is that,
whereas low-energy electrons are utilized in LEED, high-energy (30 to 100 keV) electrons are employed in RHEED. At such high energies, the mean-free-paths of the incident electrons are long (10 to 100 nm) and elastic scattering is predominantly in the forward direction. Hence, to afford the required surface sensitivity, RHEED experiments are performed at small angles (<5°) of incidence and diffraction. Energy filtering is not a requirement in RHEED because of the large energy difference between the elastically and inelastically scattered electrons; post-acceleration is likewise unnecessary as the primary electrons are sufficiently energetic to produce fluorescence on the phosphor screen.

Figure 5 shows LEED and RHEED patterns of gold films evaporated on glass and on mica;\(^{[18]}\) the film deposited on glass (at room temperature) is rough but that on mica (at elevated temperatures) is smooth and well-ordered. The ordered-surface diffraction is manifested in LEED by distinct spots and by sharp streaks in RHEED. This difference is due to the fact that, in reciprocal space, the surface layer is represented by perpendicularly-oriented rods that pass through the points in the reciprocal net. In normal-incidence LEED, only a section perpendicular through these reciprocal lattice rods is displayed, leading to the spot pattern. In grazing-incidence RHEED, a section parallel through the rods is displayed, resulting in a streak pattern. For the same reason, RHEED is unable to detect changes in periodicity along the plane of incidence. Hence, if the full two-dimensional periodicity is to be established, the sample needs to be rotated.

RHEED is most useful in studies related to the structure and morphology of thin films and surface coatings. It is possible to continuously monitor film formation under deposition conditions since the front of the sample is unimpeded by either the electron source or analyzer. In view of its low-scattering-angle geometry, RHEED is sensitive to surface asperities.

1.4 Auger Electron Spectroscopy

AES is one of the more widely used techniques for surface elemental analysis.\(^{[9–15]}\) In the Auger process, illustrated schematically in Figure 6, a core (K) level electron is emitted when a beam of electrons, typically with energies between 2 and 10 keV, is impinging onto the sample surface. In the decay process, an electron in an upper (L\(_1\)) level falls into the vacant core level and another electron
in a different upper (L_{III}) level is ejected; the latter is the Auger electron. This particular Auger process is labeled KL_{II}L_{III} in order to specify the energy levels involved. The kinetic energy of the Auger electron is dependent upon the binding energies of the K, L_{I}, and L_{III} electrons but not on \( E_p \), as shown in Equation (3):

\[
E_{KL_{II}L_{III}} = E_K - E_{L_{II}} - E_{L_{III}} - e\psi_{sp}
\]  

where \( e \) is the electronic charge and \( \psi_{sp} \) the spectrometer work function. The exact application of Equation (3) must realize that the energy difference is actually between singly ionized and doubly ionized states. Nevertheless, \( E_{KL_{II}L_{III}} \), as obtained from empirical spectra, is characteristic of a given atom, which affords AES its element-specificity. It should be noted that, although the incident electrons are of high energies, AES is still a surface-sensitive method because the emitted Auger electrons are of much lower energies that fall within the minimum of the "universal curve" (Figure 1).
a retarding field analyzer (RFA) is most affordable since it makes use of the LEED optics. The sensitivity and resolution of an RFA, however, leave much to be desired. A cylindrical mirror analyzer (CMA), Figure 7, is thus more widely used. Energy analysis with a CMA is achieved by a negative ramp voltage applied to the outer cylinder while the inner cylinder is held at ground potential. Only electrons of the appropriate energy can pass unhindered through the CMA and into the detector, which is usually a channel electron multiplier. The pass energy of the CMA is modulated and then synchronously demodulated with a lock-in amplifier; the resultant spectrum is a derivative spectrum, \( \frac{dN(E)}{dE} \), devoid of the large background. Newer instruments employ software-based modulation and filtering. Higher resolution can be achieved via a double-pass CMA or by the use of a cylindrical hemisphere analyzer (CHA), which is a double-focusing analyzer (see below).

A typical Auger spectrum is shown in Figure 8 for a Pd(100) surface exposed serially to dilute aqueous solutions of NaCl, NaBr, and NaI. For quantitative and/or molecular compositional analysis, the derivative spectrum is difficult to process. An alternative approach, the collection of nonderivative Auger spectra, involves pulse counting electronics or direct current measurements; spectra thus generated can be deconvoluted by a fast Fourier transform algorithm\(^\text{(23–25)}\) to obtain information on chemical shifts and lineshapes. Changes in Auger lineshapes reflect modifications in the valence band density of states.\(^\text{(20,21)}\)

The use of derivative Auger spectra for the determination of adsorbate surface coverages has been the subject of numerous studies.\(^\text{(22)}\) One method, the first to be used in surface electrochemical studies, makes use of Equation (4):\(^\text{(23–25)}\)

\[
\Gamma_a = \frac{I_a}{I_p \Phi_c G_a} \quad (4)
\]

where \( \Gamma_a \) is the absolute packing density (mol cm\(^{-2}\)) of the adsorbate, \( I_a \) the Auger current for the adsorbate, \( I_p \) the primary beam current, \( \Phi_c \) the measured collection efficiency of the Auger spectrometer, and \( G_a \) is the calculated Auger electron yield factor.\(^\text{(26)}\) \( I_a \) is obtained using Equation (5) by double integration of the adsorbate second-harmonic amplitude \( A_2 \) corrected for the clean-surface signal \( A_2^c \):\(^\text{(23–25)}\)

\[
I_a = \frac{4}{k^2} \int_0^E \int_0^{E_0} (A_2 - \phi_b A_2^c) dE' dE \quad (5)
\]

where \( \phi_b \) is the observed attenuation of the substrate signal by the adsorbed species, and \( k \) is the modulation amplitude. For simple adsorbates for which well-defined adlayers are available for calibration purposes, Equation (4) can be expressed in purely empirical terms by Equation (6):\(^\text{(20,21)}\)

\[
\Gamma_a = \left( \frac{I_a}{I_{aM}} \right) \frac{1}{B_a} \quad (6)
\]

where \( I_{aM} \) is the Auger signal for the clean substrate, and \( B_a \) is a calibration factor.

### 1.5 X-ray Photoelectron Spectroscopy

This technique, originally referred to as electron spectroscopy for chemical analysis (ESCA),\(^\text{(27)}\) is the other
widely used method for surface compositional analysis. In XPS, the solid surface is irradiated with X-rays which results in the ejection of a core-level electron. The kinetic energy $E_{\text{Kin}}$ of the emitted photoelectron is given by Equation (7):

$$E_{\text{Kin}} = h\nu - E_B - e\phi \tag{7}$$

where $h\nu$ is the energy of the incident X-ray photon and $E_B$ within the framework of Koopman’s theorem,$^{(11,12)}$ is the binding energy of the core-level electron. For studies with metals, it is convenient to reference $E_B$ with respect to the Fermi level; the latter is determined from the onset of electron emission at the highest kinetic energy.

The XPS source consists of an anode material which, upon bombardment by high-energy electrons, emits X-rays. The emitted radiation can be rendered monochromatic either by Bragg diffraction or by the use of the characteristic emission lines of the anode; for Mg and Al anodes, these lines are 1253.6 eV (Mg Kα) and 1486.6 eV (Al Kα), respectively. It is important to note that, for $E_B < 700$ eV, the $E_{\text{Kin}}$ of the ejected photoelectron will not fall within the minimum of the universal curve. In such a case, the surface sensitivity of XPS becomes minimal. This can be remedied either by the use of near-grazing incidence or by the detection of electrons emitted at small angles with respect to the surface plane.

To afford the high resolution required for meaningful XPS studies, energy analysis is usually based upon a CHA (Figure 9). A potential difference $U_k$ is applied across the inner and outer hemispheres of radii $R_1$ and $R_2$, respectively. Electrons of energy $eV_e$ are focused at the exit slit only if Equation (8) is satisfied:

$$U_k = V_e \left( \frac{R_2}{R_1} - \frac{R_1}{R_2} \right) \tag{8}$$

The CHA is double focusing since it focuses in two planes. The resolution of a CHA can be improved significantly by electron pre-retardation via either an RFA or a retarding lens system. XPS has also been performed with a double-pass CMA. Detection is typically done with a channel electron multiplier. Due to inherently weak intensities, signal averaging and other data processing routines are always employed.

Qualitative elemental analysis of sample surfaces relies upon the comparison of measured $E_B$ values with those for reference materials. In this regard, it is critical to note that XPS of an insulating layer (e.g. a thick oxide film) will result in a net loss of electrons and, hence, an excess of positive charge at the interface; such positive-charge excess leads to shifts in the experimental $E_B$ values. This problem can be effectively countered by irradiation of the surface, at low currents, with low-energy electrons.

Quantitative analysis is based on the fact that the ionization cross-section of a core electron is essentially independent of the valence state of the element. Hence, the intensity will always be proportional to the number of atoms within the detected volume. For quantitative purposes, the area under the background-corrected peak is taken as the intensity. The intensity is a complicated function of several parameters some of which can be eliminated by the use of a reference state analyzed under identical conditions as the sample. If the spectrometer has a small aperture and the surface is uniformly irradiated, the equation for the intensity can be simplified to Equation (9):$^{(11,28)}$

$$I_A = \sigma_A D L_{\lambda_m} I_0 N_A \lambda_m G_1 \cos \theta_1 \tag{9}$$

where $I_A$ is the integrated peak intensity for an element $A$, $\sigma_A$ the photoionization cross-section, $D$ the spectrometer detection efficiency, $L_{\lambda_m}$ the angular asymmetry of the emitted intensity with respect to the angle between the incidence and detection directions, $I_0$ the flux of primary photons, $N_A$ the density of atoms $A$, $\lambda_m$ the escape depth of the photoelectron, $G_1$ the spectrometer transmission, and $\theta_1$ is the angle between the surface normal and the detection direction.

XPS is complementary to AES. The ionization cross-section for an Auger process decreases with $E_B$; the
latter, in turn, increases with atomic number Z. Hence, AES is most sensitive for Z < 45 elements. The one distinct advantage that XPS offers is in the determination of oxidation states. This is possible because $E_B$ of the core-level electrons is influenced by changes in the chemical environment. In principle, identical information can be obtained from Auger peak energy shifts and lineshapes; in practice, however, the task is nontrivial.

XPS spectra of a smooth polycrystalline Ir foil electrode surface before and after pretreatment with iodine, are shown in Figure 10; the peaks at 62.1 and 65.2 eV represent surface iridium oxide.

1.6 High-resolution Electron Energy Loss Spectroscopy

Almost all of the incident electrons impinged at a solid surface undergo inelastic events that cause them to be backscattered at energies lower than the primary energy $E_p$. If $E_1$ is the energy lost to the surface, peaks would appear in the energy distribution spectrum (Figure 2) at energies $\Delta E = E_p - E_1$. Such peaks, commonly referred to as electron energy loss peaks, are of several types according to the origin of the energy loss. For vibrational excitations, the energy losses are small since $E_{\text{vib}} < 4000 \text{ cm}^{-1} < 0.5 \text{ eV}$. Hence, the loss peaks due to vibrational interactions lie close to the elastic peak and can be observed only if the energy loss measurements are done at high resolution.

There are two mechanisms that give rise to vibrational HREELS: dipole scattering and impact scattering. In dipole scattering, the incident electron interacts with the oscillating electric dipole moment induced by the vibration of surface species. Such interactions occur at long range and can be described either classically or quantum mechanically. Two important selection rules apply for surface dipole scattering: (i) only vibrations whose dynamic dipole moments perpendicular to the surface are nonzero contribute to HREELS spectra. This selection rule is the same as that for infrared reflection–absorption spectroscopy (IRAS); (ii) the intensity distribution with respect to scattering angle is sharply peaked in the specular direction; that is, dipole-scattering loss peaks disappear when the backscattered electrons are collected at nonspecular angles.

Impact scattering, which can only be treated quantum mechanically, involves exceedingly short-range interactions between the incident electron and the oscillator at the surface. The surface dipole selection rules do not apply to impact scattering. Theoretical considerations have predicted, and experimental studies have confirmed, the following properties of this type of scattering mechanism: (i) impact scattering vanishes in the specular direction; (ii) impact scattering is more likely to prevail at higher energies; (iii) strong dipole scatterers are weak impact scatterers; conversely, weak dipole scatterers are strong impact scatterers.

HREELS is an extremely sensitive technique. The limit of detection for strong dipole scatterers such as CO can be as low as 0.0001 monolayer; for weak scatterers such as hydrogen, the limit is 0.01 monolayer. In comparison, IRAS for chemisorbed CO, a strong absorber, is restricted to coverages above 0.1 monolayer. HREELS studies of non-CO organic molecules adsorbed at atomically smooth electrode surfaces are abundant; similar experiments using IRAS are meager. The energy accessible to HREELS ranges from 100 cm$^{-1}$ to 4000 cm$^{-1}$; IRAS detectors are not useful below 600 cm$^{-1}$. On the other hand, IRAS has higher resolution and can be utilized for experiments under electrochemical conditions.

Figure 11 shows a schematic diagram of an HREELS spectrometer.
be varied from 1 to 10 eV. To afford high resolution, energy monochromation and analysis are done either with a CMA, cylindrical deflector, or spherical deflector analyzers in combination with retarding field optics. Off-specular collection of the backscattered electrons is afforded by rotation of either the sample or the analyzer. Due to extremely low signals ($10^{-10} \text{ A}$), continuous dynode electron multiplier detectors are widely used.

An example HREEL spectrum, that of 2,5-dihydroxybenzenesulfonate chemisorbed on a Pd(100) surface, is shown in Figure 12.

### 1.7 Work Function Measurements

The work function is the energy required to remove a Fermi-level electron from the bulk to the vacuum just outside the surface.$^{(36,37)}$ In the bulk, the electron has an electrochemical potential $\mu_c$ which is equal to the Fermi energy. Once the electron is removed from the crystal and is at rest, its electrochemical potential is simply the electrostatic potential energy $-e\Phi_0$, where $\Phi_0$ is the electrostatic potential just outside the surface (where the electron does not feel its image charge). The work function is thus defined by Equation (10):

$$\phi = -e\Phi_0 - \mu_c = -e(\Phi_0 - \Phi_i) - \mu_c$$

(10)

It should be noted that the Fermi energy is not a property only of the bulk, because it contains the electrostatic potential $\Phi_i$ inside the metal, which is determined by the surface dipole layers.

In surface adsorption studies, only the surface dipole part $e(\Phi_0 - \Phi_i)$ changes, and consequently, the change in work function is equal to the change in this quantity; absolute work functions are less important. For a clean metal surface, the exponential decay of the wave function into the vacuum (electron “overspill”) creates the surface double layer. The dipole has the negative end outward, and is dependent on the surface crystallography.
Work function measurements lead to useful correlations between $\Delta \phi$ and the nature of adsorption. For example, the adsorption of an electronegative atom such as oxygen changes the surface dipole and renders the outside of the crystal more negative, thereby increasing the work function. Conversely, an electropositive adsorbate such as Cs increases the work function. For atomic adsorbates, the sign of $\Delta \phi$ is therefore correlated with the direction of charge transfer: positive $\Delta \phi$ is associated with adsorbate-to-substrate charge transfer and negative $\Delta \phi$ with substrate-to-adsorbate charge transfer. In the case of molecular adsorbates, it must be realized that the dipole moment of the molecule is a more important contributor to $\Delta \phi$ than the surface chemical bond.

Experimental measurements of $\phi$ and $\Delta \phi$ have been based upon the diode method, field emission, contact potential difference, and the photoelectric effect; the latter two are more common. The photoelectric method, which measures absolute values of the work function, is based upon the determination of the threshold energy $h\nu_0$ for photoelectron ejection; the work function is then calculated from the equation $h\nu_0 = \phi$. The contact potential difference method, which monitors changes in work function, depends on the measurement of the potential difference between two plates in electrical contact. If one of the plates is used as a reference of constant work function, $\Delta \phi$ at the other plate is manifested as a change in the contact potential. The most common way of measuring the change in contact potential uses a vibrating tip close to the surface as the reference plate (the Kelvin probe method). In its balanced condition there is an electric-field-free region between the sample and the tip, and no induced alternating current flows in the circuit. Adsorption leads to a momentary field and, hence, an alternating current. Electronic feedback is used to adjust the potential on the sample until the field-free condition again applies.

1.8 Temperature Programmed Desorption

Thermal desorption techniques\(^{(9-15)}\) exploit the fact that species adsorbed on a surface will desorb at a rate which increases with temperature; the temperature dependence of the desorption rate yields data on desorption energies which, for most cases, yield information on adsorption binding energy states. Thermal desorption can also be used to obtain surface coverages and, in combination with mass spectrometry, determine the identity of species desorbed from the surface.

Temperature-induced desorption methods can be classified according to whether the rise in temperature is fast (flash desorption) or gradual (temperature programmed desorption (TPD)). In flash desorption, the desorption rate is much greater than the rate at which desorbed gas is pumped out of the system; in this case, the desorption of a given binding state is marked by a plateau in the pressure–temperature curve. In TPD, the slow heating (desorption) rate allows the evolved gases to be pumped out; as a result, the desorption of a particular binding state appears as a peak instead of a plateau in the desorption curve. The most common method of extracting the activation energy for desorption ($E_a$) from the peak temperature ($T_p$) involves the use of the so-called Redhead equations.\(^{(38)}\) Other approaches exist that, while more rigorous, are also more difficult.\(^{(39)}\) The desorption activation energy is related to the heat of adsorption $\Delta H_{\text{ads}}$ as shown in Equation (11):

$$E_a = E_a + \Delta H_{\text{ads}}$$

where $E_a$ is the activation energy for adsorption. Several instances can be found in which the adsorption is nonactivated; for such cases, $E_a$ is equal to $\Delta H_{\text{ads}}$.

The use of a mass spectrometer to monitor species emitted from the surface simplifies TPD measurements. A comparatively inexpensive means for mass detection is afforded by a quadrupole mass analyzer, a schematic diagram of which is shown in Figure 13.\(^{(40)}\) This mass filter consists of four parallel rod-shaped electrodes arranged at the apices of a diamond. The existence of an appropriately varying electrical field between the pairs of opposite electrodes will cause all ions to impact on the rods during transit except those of a particular mass-to-charge ratio $m/z$.

In TDMS, the substrate is positioned as close as possible to the mass spectrometer; provision must be made to minimize temperature gradients at the sample surface. The temperature is monitored by a thermocouple wire placed in direct contact with the crystal. Problems associated with degassing from parts of the sample
manipulator close to the crystal can be solved by masking the mass spectrometer with a small aperture such that only line-of-sight detection is possible. Microprocessor control allows multiplexed data acquisition.

A thermal desorption mass spectrum is shown in Figure 14 for CO desorbed from a Pd(111)–c(4 × 2)–CO adlattice.

1.9 Instrument Designs

The single most critical step in UHV/EC experiments is the transfer of the electrode between the electrochemical cell (at ambient pressures) and the surface analysis chamber (under ultrahigh vacuum (UHV)). Ideally, the transfer is not accompanied by changes in surface structure and/or composition. The simplest approach, transfer through air, is applicable only if the surface is inert (such as an oxide film) or is covered with a protective film (of solvent or electrolyte) that can be removed by evacuation inside the UHV chamber. An alternative procedure that would allow electrode transfer in a controlled environment makes use of an inert-atmosphere glovebox attached to the surface-analysis instrument; electrochemical experiments are performed inside the box. However, regardless of the purity of the inert gas, the environment is not free of contaminants since the walls of the glovebox are replete with impurities that are slowly desorbed. The transfer-through-air and drybox methods have been used extensively in XPS and AES studies with oxidized or chemically modified polycrystalline surfaces; neither has been adopted for single-crystal work.

The approach employed most successfully in UHV/EC studies of single-crystal electrode surfaces involves the fabrication of a multi-technique surface-analysis apparatus to which an electrochemistry chamber is physically appended. The entire assembly is constructed of stainless steel and can be baked to about 200 °C in UHV to attain ultra-clean conditions. UHV is maintained by a combination of a titanium sublimation pump and either an ion or a turbomolecular pump. Transfer of the electrode between the analysis and electrochemistry chambers is accomplished by a sample manipulator-translator. In some instruments, the crystal remains attached to the same sample holder as it is moved between the two compartments; in other systems, the crystal is actually transferred between two different manipulators. A gate valve isolates the electrochemistry compartment, whenever necessary, from the rest of the system. It is preferable to keep the electrochemistry chamber under UHV when not in use in order to preserve its cleanliness. The electrochemical cell itself is located inside a bellows-enclosed compartment separated from the electrochemistry chamber by another gate valve; the cell is inserted only after the electrochemistry chamber is brought to ambient pressures with ultra-high purity inert gas. Based upon these considerations, various types of UHV/EC instruments have been constructed four of these are shown in Figures 15–17 for illustrative purposes.

In the UHV/EC system depicted in Figure 17, an isolable, differentially pumped antechamber is situated between the UHV and electrochemistry compartments. The main function of this antechamber is to minimize the influx of solvent and/or electrolyte vapor into the surface analysis compartment. In this context, it is important to mention that the pressure in the electrochemistry chamber is usually an order of magnitude higher than in the UHV chamber; mass spectrometric analysis of the residual gas has revealed that the pressure difference arises primarily from higher amounts of water in the electrochemistry compartment. Because water is only weakly surface-active, it is generally not of major concern in UHV/EC studies. However, in the presence of comparatively high quantities of water, impurity species may be dislodged from the walls of the chamber and onto the sample surface. Similar “knock-off” effects can arise when the chamber is backfilled with high purity inert gas. Hence, it is critical to maximize the cleanliness of the electrochemistry chamber and its associated manifold; this can be accomplished by frequent bakeout and continuous evacuation of the electrochemistry chamber when it is not in use.

It is also important to ensure that the backfill gas is of the highest purity to minimize surface contamination by trace-level impurities; argon of at least 99.99% purity is usually employed. Background contamination is metal specific; for example, Cu is more sensitive to residual O

Figure 14 Thermal desorption mass spectrum of Pd(111)–c(4 × 2)–CO.
while Pt is more susceptible to carbonaceous impurities. Hence, depending upon the nature of the investigation, it may be necessary to pass the high-purity inert gas through molecular scavengers (e.g. a Ti sponge heated to 900°C) for still further purification. It must also be realized that electrode-surface contamination can also result from trace-level impurities in the electrolyte solution. Such impurities can originate from the solvent, electrolyte, glassware, and/or the inert gas employed for solution deaeration. The level of solution-based impurities can be minimized by the use of highly purified chemical reagents and gases; in the case of aqueous solutions, the utilization
of pyrolytically triply distilled water is recommended, although the use of water eluted through (commercial) multiple-filtration stages is now an acceptable alternative.

A typical UHV/EC experiment following instrument "bakeout" (at which point the base pressure should be less than $5 \times 10^{-10}$ torr) would include the following steps. After surface preparation and characterization, the electrode is transferred into the electrochemistry chamber (cf. Figure 17) which, by closure of the main gate valve, is isolated from the UHV system and then backfilled with high-purity inert gas. The external gate valve is opened and the cell is inserted into the electrochemistry chamber. After completion of the electrochemical experiments, the cell is retracted, the external gate valve closed, and the chamber evacuated by a liquid helium cryogenic or turbomolecular pump to less than $10^{-6}$ torr. At this point, the main gate valve can be opened to complete the evacuation of the electrochemistry chamber and permit the transfer of the electrode into the analysis compartment. Pumpdown from ambient pressure to $10^{-8}$ torr vacuum is usually achieved in less than 15 min.

Electrochemistry experiments have been performed with cells in either the standard or thin-layer arrangement. The latter significantly reduces the level of surface contamination from solution-borne impurities. If the entire electrode is to be immersed in solution, all faces of the single-crystal should be oriented identically in order to obtain voltammetry characteristic of only one
crystallographic face. As an alternative, the electrode can be positioned on top of the electrochemistry cell in such a way that only one crystal face is exposed to solution (Figure 18). Such a configuration, however, often results in the adherence of a droplet of electrolyte on the crystal surface when the electrode is withdrawn from the solution; this problem does not arise if the electrode is withdrawn slowly (1 mm s⁻¹) in the vertical position, as the droplet would then form at the bottom of the crystal.

2 FUNDAMENTAL ASPECTS

2.1 The Emersion Process

It is important to determine the changes at the electrode–electrolyte interface when the electrode is emersed (removed at a given potential) from the electrolyte solution. In the ideal process, the emersed electrode retains an interfacial layer identical in composition and structure to that when the electrode was still in solution. The electrode–solution interface, or the electrochemical double layer, is a structured assembly of solvent, electrolyte, and reactant. In the traditional view, this ensemble, nominally 1 nm in thickness, is subdivided into an inner (compact) layer that consists of field-oriented adsorbed solvent molecules and specifically adsorbed anions, and an outer layer composed of solvated cations. The locus of the centers of the adsorbed anions delineates the so-called inner Helmholtz plane (IHP), whereas the line of centers of the nearest solvated cations defines the outer Helmholtz plane (OHP). Charge transfer reactions are thought to occur at this outer (reaction) plane. The solvated ions interact with the charge metal only through long-range electrostatic forces and, because of thermal agitation in the solution, are distributed in a three-dimensional region that extends from the OHP into the bulk of the solution. This region is identified as the diffuse layer, and its thickness is a function of electrolyte concentration; it is less than 30 nm for concentrations greater than 10⁻² M.

Clearly, the electrode-withdrawal process involves a delicate balance with respect to the thickness of the emersion layer: it must be sufficiently thick to incorporate the intact electrochemical double layer but it should also be thin enough to exclude residual (bulk) electrolyte. Numerous studies have helped establish the fact that the electrochemical double layer can, under appropriate electrolyte concentrations, be retained intact when the electrode is withdrawn from solution under potential control. The optimum concentration depends upon whether emersion is hydrophobic or hydrophilic. For the latter type, the concentration must not be much higher than 10⁻³ M if inclusion of bulk electrolyte is to be circumvented. For hydrophobic emersion, the concentration must not be much lower than 10⁻² M if double-layer discharge is to be avoided. In cases where the mode of emersion is not known, an electrolyte concentration of 10⁻³ M appears to be a logical choice.

Investigations of hydrophobic emersion based upon electrode resistance measurements, XPS, and work function changes have been able to: (i) demonstrate the existence of an emersed double layer; (ii) determine its stability; and (iii) monitor changes in its structure and composition brought about by the emersion process. The evidence has been compelling that the structure and composition of the double layer in the emersed phase are very similar, if not identical, to those in the solution state; that is, only a little or no double-layer discharge occurs upon emersion. Later studies focused on the effect of the emersion process on the structure of adsorbed molecular species; the data obtained demonstrate that the structure and orientation of molecular adsorbates are essentially unperturbed by the emersion process.

2.2 Perturbations Caused by Evacuation and Surface Analysis

Another important issue in UHV/EC centers around the perturbations caused by the evacuation and subsequent surface analytical processes. Alterations in the surface electronic structure can be studied by work function change measurements; representative results are shown in Figure 19, in which a plot of the work function of a polycrystalline Au emersed from 0.1 M HClO₄ into UHV as a function of the emersion potential is presented. It can be seen here that the work function tracks the applied potential over a wide range, even into the oxide formation region. This, and other sets of pertinent data, demonstrates that the electronic properties of the electrochemical double layer are unaffected by emersion into either the ambient or UHV.

An expected effect of evacuation are changes in composition due to UHV-induced desorption; the extent will depend upon the heats of vaporization ΔH_vap or sublimation ΔH_sub of the unbound materials (excess water, unadsorbed gases, liquids, and sublimable solids) entrapped within the emersed layer. Water retained as part of the hydration sphere can survive the evacuation process if the hydration enthalpies ΔH_hyd are substantial. Strongly chemisorbed species, such as iodine at the noble-metal electrodes, are expected to form stable well-ordered adlattices in solution that would not reconstruct in vacuum. Similarly, the coverages and structures of irreversibly adsorbed molecules are expected to withstand the evacuation process. One
example is provided by 3-pyridylhydroquinone (Py-H$_2$Q) which, on Pt(111), is chemisorbed through the N-heteroatom.$^{77}$ In such a mode of surface attachment, the diphenol group is pendant and able to undergo reversible quinone/hydroquinone redox reaction. It has been shown that the redox current–potential curves for chemisorbed Py-H$_2$Q, before and after a 1-h exposure to UHV, are identical (Figure 20)$^{77}$

Perturbations can also arise from the surface analysis itself. For example, implicit in TPD is the requirement for complete desorption; hence, TPD and TDMS are inherently destructive techniques. On the other hand, analytical methods based upon electron and optical spectroscopies are not intended to damage the surface layer. Unless exceedingly high photon fluxes are used, optical methods are nondeleterious when compared with particle-based techniques. Several surface processes are known to be stimulated by electron impact. Examples are binding-site conversions, dissociative chemisorption, and particle desorption.$^{12}$ Such processes take place even at minimal sample heating (low electron power densities), which indicate that surface thermal effects are insignificant. It is now accepted that electron-stimulated reactions occur mainly via electronic excitations. These excitations can lead to bond dissociation and form the basis of the surface spectroscopic technique known as electron stimulated desorption ion angular distribution (ESDIAD)$^{78}$

Pendant functional groups not directly bonded to the substrate surface, such as the diphenol moiety in Py-H$_2$Q, are most prone to electron-stimulated desorption. In other instances, electron irradiation can induce surface displacement reactions that involve species present as residual gas in the analysis chamber. It has been reported, for example, that prolonged electron-beam irradiation during LEED and/or AES in the presence

---

of residual water vapor caused a Ba(CN)₂ adlayer to undergo a reaction that formed gaseous HCN and solid Ba(OH)₂.\(^{72,73}\)

Even if changes in the emersed double layer are induced by the surface analysis, it must be realized that such alterations would be deleterious only if the post-analysis layers are to be used for further experiments. In those instances when additional experiments have to be performed, it is a simple matter to regenerate the surface to exactly the point just prior the surface analysis. If desired, beam damage can be assessed by repeated analysis over a period of time followed by extrapolation of the data to zero time.

### 3 REPRESENTATIVE STUDIES

UHV/EC investigations with single-crystal electrode surfaces can be broadly classified into three groups. The first is focused on the structure and constitution of the electrochemical double layer as functions of electrode potential and solution composition. The second centers on electrodeposition and dissolution processes; included in this category are extensive studies on hydrogen and oxygen adsorption/desorption. The third deals with the interfacial structure and reactivity of chemisorbed molecules.

#### 3.1 Electrochemical Double Layer

Two general strategies have been adopted in UHV/EC studies of the electrical double layer. One, strictly a model approach, involves the synthesis of the double layer in UHV by sequential cryogenic adsorption of its constituents; the temperature must be maintained below 160 K at all times in order to prevent the evaporation of unbound solvent. The other approach is based upon the structural and compositional analysis of the emersed layer; since surface characterization is done at ambient temperatures, excess water in the diffuse layer is pumped away.

The viability of the cryogenic coadsorption approach was first demonstrated by comparison of work-function changes \(\Delta \phi\) for UHV-synthesized and actual Ag(110) – H₂O layers, where X denotes Cl⁻ or Br⁻. The results showed that, as long as coadsorbed water is present in the cryogenic layer, good agreement exists between the ex situ and in situ results. The satisfactory agreement indicates that, at least under zero diffuse-layer-charge conditions, information from the UHV simulation work may have relevance to actual electrochemical systems. The requirement of solvation implies that the electronic properties of the unsolvated Ag(110) – Br interface are not identical to those of the fully solvated Ag(110) – Br – H₂O layer. Other more complex interfacial systems have also been modeled via cryogenic coadsorption. For example, UHV-synthesized H₂O – HF – CO coadsorbed layers were studied at Pt(111) and Rh(111) surfaces by HREELS, LEED, TPD and XPS.\(^{83,84}\) In such work, the “control” of electrode potential was based upon the amount of coadsorbed H₂. The cryogenic coadsorption approach offers two main advantages: (i) the control of interfacial parameters far more precisely than can be achieved in solution; and (ii) the detailed characterization of fully solvated species by a host of surface-sensitive spectroscopic methods. The approach, however, provides little beyond structural models for the interfacial layers; its usefulness as a surface analytical technique is unclear.

The direct approach to the study of the electrochemical double layer involves the characterization of the electrolyte layer retained at the emersed surface. This approach is applicable only to cases in which the compact layer consists of materials that remain on the surface even after evacuation to UHV. For example, only limited information can be expected when emersion is from aqueous HF since both H₂O and HF will be completely desorbed, at ambient temperatures, in vacuum. It is also implied that the molecules pumped away are inconsequential in the formation and preservation of the electrochemical double layer. This is not an unreasonable premise since the double layer composed of chemisorbed species is governed by strong chemical bonds, and should only be minimally perturbed by physisorbed species.

UHV/EC studies of anions specifically adsorbed from aqueous solutions have been carried out at well-defined Pt(111),\(^{96–92}\) Pt(100),\(^{93,94}\) stepped Pt(6)[6(111) × (111)]\(^{95}\), Cu(111),\(^{96}\) Ag(111),\(^{97}\) Au(111),\(^{98}\) and Pd(111)\(^{99}\) electrodes. The anions studied include the halides,\(^{86–96,93–99}\) SH⁻,\(^{89,99}\) CN⁻,\(^{91,92}\) SCN⁻,\(^{100}\) and SO₄²⁻.\(^{96}\) All of these anions yield surface coverages and well-ordered structures that depend upon the solution pH and the applied potential.

#### 3.2 Underpotential Electrodeposition and Anodic Dissolution

The deposition of monolayer quantities of one metal onto another generally occurs at potentials positive of that for bulk deposition because of preferential interactions between the substrate and the foreign-metal electrode. The underpotential deposition (UPD) process is strongly influenced by the structure and composition of the substrate; hence, UPD research is an area in which UHV/EC methods have been widely adopted. The published literature on UHV/EC studies of UPD can be categorized according to whether the experiments were used to correlate substrate structure with...
the electrodeposition voltammograms, or to determine the interfacial properties of the adatom-modified substrate. Investigations devoted to structure–voltammetry correlations help establish reference states against which new experiments can be calibrated; those focused on post-deposition characterization yield important information concerning the electrocatalytic selectivity of the mixed-metal interfaces.

The first applications of LEED and AES in electrochemistry involved the correlation of the surface crystallographic orientation with the underpotential hydrogen deposition at Pt electrodes. Those studies were motivated by earlier work with polycrystalline Pt electrodes whose cyclic voltammograms showed two hydrogen deposition peaks; the peaks were identified simply as weakly and strongly bound states of adsorbed hydrogen. Subsequent studies with single-crystalline but uncharacterized Pt(111), Pt(110), and Pt(100) electrodes associated the weakly bound hydrogen peak with the Pt(111) electrode, and the strongly bound hydrogen with the Pt(100) electrode. These studies, though not definitive enough due to the existence of atomically disordered surfaces because of multiple oxidation–reduction cycles, provided the impetus for further UHV/EC studies.

Later work based upon flame-annealed single-crystal surfaces led to the discovery of new voltammetric features for Pt(111) in the form of highly reversible pseudocapacitance peaks at potentials well positive of the usual hydrogen deposition peaks. UHV/EC studies that employed apparatus equipped with improved UHV-to-EC transfer technology were able to reproduce the new voltammetric results. Extensive follow-up work then ensued that clarified several aspects of this surface-sensitive reaction.

While studies of hydrogen chemisorption at Pt single-crystal electrode surfaces have been extensive, investigations on the formation of underpotential states of oxygen have not been as numerous. Electrochemical experiments have been performed only with Pt(100) and Pt(111) electrodes. Gas-phase and solution-state reactions with oxygenous species have been carried out at stainless-steel single crystals. The occurrence of place-exchange during anodic film formation has been studied via LEED spot-profile analysis. This irreversible place-exchange reaction accounts for the observation that the electrode surface loses its single crystallinity even after only minimal anodic oxidation.

The literature on monolayer metal deposits is extensive. Most of the work pertains to the geometric, electronic, and catalytic properties of foreign metals vapor deposited in UHV onto single-crystal substrates; a compilation of the adlattice structures of such metal adlattices has been published. Studies of foreign metal monolayers deposited electrochemically have been primarily with polycrystalline substrates. The first UHV-based investigation of electrodeposited admetals employed XPS to determine the core-level shifts of submonolayer Cu and Ag on polycrystalline Pt. Quite a few investigations have been reported of admetal deposits on single-crystal surfaces but only a minority of these involve UHV/EC technology.

The first UHV/EC work on electrodeposition at well-defined electrode surfaces involved Ag at an iodine-coated Pt(111) electrode. The iodine pretreatment was done in UHV to form a protective Pt(111)($\sqrt{3} \times \sqrt{3})R19.1^\circ$ adlattice before immersion into a solution containing dilute Ag⁺ in 1 M HClO₄. Subsequent studies included Ag electrodeposition on I-coated Pt(100) and stopped Pt(s)[001] (111). Cu on I-pretreated Pt(111), and Pb on I-covered Pt(111). Sn(122) and Pb(123) deposition onto iodine-free Pt(111) in Br⁻ or Cl⁻ solutions has also been studied. Although the Pt substrate was not pretreated with I, the presence of halide ions in the plating solution led to specific adsorption of anions prior to the deposition process.

Electrodeposition from solutions free of surface-active anions has been studied. These investigations, carried out in ClO₄⁻ or F⁻ electrolyte, included UPD of Cu on Pt(111), Ti, Pb, Bi, and Cu on Ag(111). Invariably, the underpotentially deposited films showed unique adlattice geometries that were dependent upon the substrate orientation and the admetal coverage.

The atomic layer epitaxy (ALE) approach to deposition of a compound film, based upon the alternate layer-by-layer deposition of the elements of the compound, has been adopted in the electrochemical synthesis of compound semiconductors. This electrochemical analog, referred to as electrochemical atomic layer epitaxy (ECALE), takes advantage of the fact that only monolayer quantities are produced by UPD. For example, the UPD-based epitaxial growth of CdTe on Au(111) has been monitored by LEED and AES.

While UHV/EC-based investigations on electrodeposition abound, little has been published on the reverse reaction, anodic dissolution; most of the studies reported have made use of electrochemical scanning tunneling microscopy (ECSTM). One system, that of the adsorbate-catalyzed corrosion of Pd, has been extensively studied using both UHV/EC and ECSTM. In the absence of a layer of chemisorbed iodine, anodic dissolution of Pd in sulfuric acid yields only a passivating metal oxide film; when iodine is chemisorbed on the surface, dissolution of Pd occurs without alteration of the structure or composition of the iodine adlattice (Figure 20).
3.3 Molecular Adsorption

The capability to prepare single-crystal surfaces by thermal treatment at ambient pressures has fostered the proliferation of non-UHV studies of the adsorption of molecules at monocrystalline electrodes. The detail of information obtained from such in situ work, however, falls short of that provided by UHV/EC experiments. As one example, although in situ IRAS has provided much information about the structure-sensitivity of the chemisorption and anodic oxidation of CO, its sensitivity is too low to permit meaningful investigations with other molecules as simple as ethylene.

3.4 Solvent–Electrode Interactions

The nature of the interactions between the solvent and the electrode surface has significant ramifications in electrochemical surface science. For instance, the use of strongly surface-active solvents would severely repress electrocatalytic processes that rely on a direct interaction between the reactant and the metal surface. The bonding of water to metal surfaces is an important issue in aqueous electrochemistry. In models suggested to explain the potential dependence of double-layer capacity, the existence has been postulated of monomeric and clustered water molecules, both of which are able to adopt two opposite dipolar orientations. The studies of water adsorption on single-crystal electrodes are all based upon vapor deposition in UHV, usually at cryogenic temperatures since water is not adsorbed on clean metal surfaces at ambient temperatures. Of significant interest to electrochemistry is the observation that, on Ni, Pt, Ag, Cu, and Pd, water is dissociatively chemisorbed if the surface contains submonolayer coverages of oxygen. The reaction is thought to occur by hydrogen abstraction. This reaction is metal-specific since at other noble metals such as Ru(001), adsorbed oxygen is inactive towards water dissociation.

Nonaqueous solvents commonly used in electrochemistry include acetonitrile, dimethylformamide, p-dioxane, sulfolane, dimethylsulfoxide, pyridine, acetic acid, propylene carbonate, liquid ammonia, and dichloromethane. Work on such materials can be categorized according to how the electrode is allowed to interact with the nonaqueous solvent: by vapor dosing in vacuum, or by exposure to aqueous solutions containing small quantities of nonaqueous-solvent material. Studies under the latter category are more abundant, but those are more accurately classified under electrode–solute, not electrode–solvent, interactions. Except for one case, all UHV-based studies with nonaqueous-solvent compounds were carried out purely in the context of gas–solid interactions. The intent of the one exception was...
to use the reactions between the solvent vapor and the metal surface as models for the electrochemical analogs; for better simulation of solution conditions, vapor dosing was up to 0.3 torr, approaching the vapor pressures of the liquid solvents. UHV/EC work in which the electrode is immersed in pure nonaqueous solvent has not been pursued.

3.5 Group IB Electrodes

Most organic compounds are only weakly adsorbed on Cu, Ag, and Au electrode surfaces; hence, unless the adsorbate itself is a solid or when adsorption is carried out at cryogenic temperatures, meaningful UHV/EC experiments with the coinage metals are limited. One study, which took advantage of the strong interaction of the -SH functional group with the coinage metals, used HREELS, LEED, AES, and voltammetry to determine the influence of the location of the N heteroatom on the adsorption properties of the isomers 2-mercaptopyridine and 4-mercaptopyridine at Ag(111) in aqueous HF. The subject compounds were thought to undergo isomerization upon oxidative adsorption through the -SH moiety.

3.6 Group VIII Electrodes

The abundance of studies of organic molecular adsorption at electrode surfaces involves the platinum metals. This is not surprising since these metals are well known for their electrocatalytic activities and an immense body of work has already been amassed for these materials in their polycrystalline states. Surface electrochemical studies of metal-organic compounds at single-crystal electrodes can be broadly classified according to whether the work was done with CO (and related small molecules) or with more complex molecules. The former are more numerous, although a vast majority of the studies have been carried out without UHV-based surface characterization. Work with well-defined surfaces have been limited to LEED of CO adlattices on Pt(111) and Pd(111), and HREELS, LEED, TPD and XPS of mixed H₂O–HF–CO layers generated in UHV by cryogenic adsorption at Pt(111) and Rh(111) surfaces.

An impressive amount of detailed information on a wide variety of complex organic compounds chemisorbed at well-defined Pt(111) and Pt(100) electrode surfaces has been furnished by LEED, AES, TPD, and HREELS. Electrocatalytic reactivity studies which accompanied these investigations were limited to anodic oxidation reactions; only correlations between the mode of adsorbate bonding and the extent of anodic oxidation were attempted.

3.7 Carbon Monoxide

Much of what is known about the structure and reactivity of CO chemisorbed at single-crystal electrodes, and their dependencies on surface crystallographic orientation, electrode potential, and adsorbate coverage are based almost entirely upon in situ IRAS measurements. Two UHV/EC studies on CO are noteworthy. One made use of a well-defined Pt(111) surface and sought to correlate anodic peak potentials with observed LEED structures. The other, based upon LEED, AES, TPD, voltammetry, and coulometry, examined the chemisorption of CO at well-defined and anodically disordered Pd(111). In this study, it was shown that CO adsorption from solution onto a UHV-prepared Pd(111) surface yielded an ordered adlattice, Pd(111)–c(4 × 2)–CO, in which the CO molecules occupy two-fold hollow sites. Two CO-to-CO₂ anodic oxidation peaks were observed: the first peak is partial oxidation of the c(4 × 2) layer followed by an adlattice reconstruction to form a Pd(111)(√3 × √3)R30°–CO structure; the second peak is due to complete oxidative desorption of the Pd(111)(√3 × √3)R30°–CO adlayer to yield a clean and well-ordered Pd(111) single-crystal surface. At the surface disordered by extensive anodic oxidation, chemisorption of CO occurred spontaneously but no ordered CO adlayers were produced; on the disordered surface, the CO molecules were thought to reside on atop sites.

3.8 Other Organic Compounds

UHV/EC investigations with organic compounds more complex than CO have been focused on the nature of the adsorbate–substrate chemical interactions as a function of interfacial parameters, and on the influence of the mode of attachment on the reversible and/or catalytic electrochemistry of the adsorbed species. For example, the differences between gas-phase and solution-state chemisorption and catalytic hydrogenation of ethylene have been documented: variations in the structures of ethylene chemisorbed at the solid–solution and gas–solid interfaces lead to different reaction pathways. In solution, ethylene chemisorption occurs molecularly through its π-electron system, whereas chemisorption in UHV is accompanied by molecular rearrangements to form a surface ethyidyne species. In electrocatalytic hydrogenation, ethylene is reduced on the Pt surface by adsorbed H atoms; in gas-phase hydrogenation, H atoms must be transferred from the Pt surface through a layer of reversibly adsorbed ethylydine to ethylene adsorbed on top of the ethylydine layer. Further work with alkenes has centered on the effects of hydrocarbon chain length and the presence of weakly surface-active substituents such as
carboxylates and alcohols. These studies showed that: (i) the primary mode of surface coordination of terminal alkenes, alkenols, and alkenoic acids is through the olefinic double bond; and (ii) the pendant alkyl chain is always extended outward on top of the propylene moiety. From coulometric measurements, it was concluded that anodic oxidation of the chemisorbed alkenes is limited to the anchor group, unless the pendant moieties are too close in close proximity to the electrode surface.

Early studies with smooth polycrystalline Pt indicated that aromatic compounds such as 1,4-dihydroxybenzene are chemisorbed in discrete, nonrandom orientations that depend upon various interfacial parameters. Subsequent UHV/EC experiments with well-defined Pt(111) electrodes supported the earlier findings, although the conditions at which the multiple orientational transitions occur are different for the polycrystalline and single-crystal electrodes. The electrocatalytic oxidation of multiply oriented aromatic molecules has been shown to be strongly dependent on their initial adsorbed orientations.

Sulfur-containing compounds investigated include thiophenol, pentafluorothiophenol, 2,3,5,6-tetrafluorothiophenol, 2,3,4,5-tetrafluorothiophenol, 2,5-dihydroxythiophenol, 2,5-dihydroxy-4-methylbenzyl mercaptan, and benzyl mercaptan; chemisorption of these compounds occurs oxidatively through the sulfur group with loss of the sulfhydryl hydrogen. The tethered diphenolic moieties in the adsorbed dihydroxythiophenols show reversible quinone/diphenol redox chemistry. The S-heterocyclic compounds studied were thiophene, bithiophene, and their carboxylate and methyl derivatives. Experimental evidence indicates that these compounds are bound exclusively through the S heteroatom, although the chemisorption process may be accompanied by self-desulfurization. The electropolymerization of 3-methylthiophene at clean Pt(111) and monomer-treated Pt(111) pretreated has been studied, and the properties of the two types of polymer film were compared. In terms of the HREELS spectra, two major differences were noted which were attributed to changes in the physical nature of the polymer film.

The chemisorption of pyridine, bipyridine, multi-nitrogen heteroaromatic compounds, and their derivatives has been examined as a function of isomerism and substituents. Pyridine forms a well-ordered layer of admolecules chemisorbed through the N heteroatom in a tilted vertical orientation. The derivatives are coordinated similarly unless the ring nitrogen is sterically hindered such as in 2,6-dimethylpyridine where chemisorption is in the flat orientation. Pyrazine, pyrimidine, and pyridazine are chemisorbed through only one nitrogen heteroatom in a tilted-vertical orientation. For the derivatives, adsorption occurs through the least hindered ring nitrogen. Carboxylate substituents located in positions ortho or meta to the nitrogen heteroatom interact with the Pt(111) surface at positive potentials. The chemisorbed layers were disordered as indicated by the absence of LEED patterns and were observed to be electrochemically unreactive. The adsorption behavior of the bipyridyls was found to be sensitive to steric hindrance at the
positions ortho to the nitrogen heteroatom. Studies on the mode of chemisorption at well-defined Pt(111) of L-dopa, L-tyrosine, L-cysteine, L-phenylalanine, alanine, and dopamine have been reported.\(^{167,168}\)

The chemisorption of aromatic molecules on well-defined Pd(hkl) surfaces has recently been studied by a combination of UHV/EC and ECSTM.\(^{169,170}\) Figure 23 shows a high-resolution STM image of a Pd(111) electrode immersed in a dilute solution of 1,4-dihydroxybenzene; Figure 24 shows the corresponding HREEL spectrum. Analysis of both sets of data indicate that hydroquinone is oxidatively chemisorbed as benzoquinone and, although bound in the flat orientation, is slightly tilted.\(^{170}\)

4 EPILOGUE

The aim of modern electrochemical surface science is the design of superior electrode materials not only for the characterization but also for the control of important electron-transfer reactions. This goal can best be accomplished by the establishment of fundamental correlations between the structure, composition and chemical reactivity at the electrode–solution interface. As should be evident from the above review and the cited literature, the UHV/EC approach provides an arsenal of surface-sensitive techniques that help in the establishment of such fundamental correlations.

The UHV/EC approach offers three essential functions: (i) it can be used to tailor surfaces of well-defined structure and composition for the performance of specific electrochemical tasks; (ii) it can be employed to determine (or model via cryogenic deposition of the constituent species) the structure and composition of the compact layer; (iii) it can be exploited to interrogate the composition and lateral structure of nonspecifically absorbed materials in the diffuse layer. These tasks will always be paramount in fundamental electron-transfer investigations, whether those are directed towards biotechnology, electroanalysis, fuel-cell technology, or materials research. That UHV/EC-based results have been supported and complemented by in situ experiments essentially assures the continued utilization of this approach in future studies centered around the electrode–electrolyte interface.

APPENDIX 1

Ultrahigh Vacuum Electrochemistry Bibliography

Presented in this Appendix is a near-exhaustive bibliography of UHV/EC-based investigations of single-crystal electrodes published since 1991. A compilation of earlier work has been published previously (G.J. Cali, J.R. McBride, M.P. Soriaga, Prog. Surf. Sci., 39, 422 (1992)). Owing to space limitations, no listing is provided for studies with polycrystalline electrodes which are more numerous. Dr Y.-G. Kim and Dr J.E. Soto assisted in the compilation of this bibliography.

1 Principles and Objectives of Ultrafast Electrochemical Techniques

1.1 Introduction
Irrespective of the approach taken, from the detection of highly reactive intermediates to the tantalizing possibility of directly probing the energetics and dynamics of facile electron transfers, ultrafast electrochemical techniques are revolutionizing investigations into redox processes. In doing so, they promise to revolutionize the type, quality and range of information available to test and develop new theories of electron transfer. Moreover, these high-speed approaches will allow new devices to be developed, such as sensors that exploit differences in reaction dynamics rather than energetics to achieve a selective response.

1.2 The Need for Speed
Many significant electrochemical events, such as electron and proton transfers, ligand exchanges, isomerizations, and ejection of leaving groups, occur on the low microsecond and nanosecond time domains. To achieve a meaningful insight into these redox processes, it must be possible to measure rate constants under a wide range of experimental conditions, such as driving force, temperature and so on. However, conventional electrochemical methods cannot fulfil this role since they are restricted to millisecond, or longer, timescales. Thus, while modern laser-based spectroscopy has provided a powerful new insight into chemical processes that occur at picosecond and even femtosecond timescales, it is only recently that (E) and coupled chemical (C) reactions. Ultrafast electrochemical techniques now allow it to do so at times as short as 10 ns. In transient measurements, decreasing the lower accessible timescale depends critically on fabricating ultramicroelectrodes that continue to respond ideally as their critical dimension (e.g. the radius of a microdisc) decreases. It is now possible to assemble microelectrodes that respond to changes in applied potential within less than a few nanoseconds. In steady-state approaches, ultrasmall probes are required to make short timescale measurements and various approaches that yield nanodes (i.e. electrodes of nanometer dimension) have been proposed. However, beyond the need for smaller probes and faster instrumentation, the continued development of new theory describing electron transfer is essential, where the dimensions of the zone that is depleted of reactant because of a Faradaic reaction and the electrochemical double layer become comparable.
electrochemists have meaningfully probed redox processes occurring on the submicrosecond timescale.

The objective of this article is not to provide an extensive catalogue of recent studies conducted in this area. Rather, the intention is to describe the theory and practice of ultrafast electrochemical techniques, to convey a sense of the current state of the art in the area, and to look at likely future developments.

Much of our discussion will focus on microelectrodes; the ability routinely to fabricate electrodes with radii smaller than one hundredth of the thickness of a human hair has profoundly changed the way electrochemistry is undertaken. The impact of microelectrodes in redefining the spatial and time limits of electrochemistry began in the late 1960s with Fleischmann’s pioneering work. Since the 1970s, researchers have used these ultrasmall probes to study the kinetics and mechanism of fast heterogeneous electron transfers and homogeneous chemical reactions, to extend the range of electroanalytical measurements, to map redox activity topographically using scanning electrochemical microscopy (SECM), and to provide platforms for the fabrication of sensors for both in vitro and in vivo applications.

2 DIRECT ELECTROCHEMICAL METHODS

2.1 Microelectrode Fabrication and Characterization

Microelectrodes are miniature electrodes where the critical electrode dimension is less than about 10 µm yet remains much greater than the thickness of the electrical double layer, which is typically 10–100 Å (1 Å = 10⁻¹⁰ m). The physicochemical properties of microelectrodes are distinctly different from the properties observed for macroelectrodes and from those predicted for electrodes whose dimensions approach the molecular level. Although microelectrodes have been used since the 1940s, e.g. to measure oxygen concentrations within tissue, it is only since the 1980s that the availability of microscopic gold and platinum wires has allowed them to be widely used.

Figure 1 illustrates the five common microelectrode geometries. The microdisc is the most popular geometry and is employed in approximately 50% of all investigations. Other common geometries include cylinders (20%) and arrays (20%), with the remaining 10% comprising bands and rings and less frequently spheres, hemispheres, and more unusual assemblies. The most popular materials include platinum, carbon fibers, and gold, although mercury, iridium, nickel, silver, and superconducting ceramics have also been used. Microdisc electrodes predominate because of their ease of construction and because the sensing surface of the electrode can be mechanically polished. Microelectrodes in the form of discs, cylinders, and bands are commonly fabricated by sealing a fine wire or foil into a nonconducting electrode body such as glass. Microlithographic techniques are perhaps the best method of producing well-defined microelectrode arrays. Other array fabrication methods include immobilizing large numbers of metal wires within a nonconducting support and electrodeposition of mercury or platinum within the pores of a polymer membrane. Spherical and hemispherical microelectrodes are typically formed by electrodepositing mercury onto platinum or iridium microdiscs.

2.2 Cell Time Constants

Every electrochemical measurement has a lower timescale limit that is imposed by the RC cell time constant, i.e. the product of the solution resistance, R, and the double layer capacitance, C, of the working electrode. Meaningful electrochemical data can only be extracted at timescales that
are longer than the cell time constant, typically five to ten times the $RC$ time constant. Therefore, an important objective when seeking to make high-speed transient measurements is to minimize the cell time constant.

As discussed in detail by Newman and described in Equation (1), the solution resistance for a disc-shaped ultramicroelectrode is inversely proportional to the electrode radius,

$$R = \frac{1}{4kr}$$

where $\kappa$ is the conductivity of the solution and $r$ is the radius of the microdisc. Equation (1) shows that $R$ increases as the electrode radius decreases. Thus, changes in the cell resistance with decreasing electrode radius do not have the desired effect of reducing the $RC$ cell time constant.

Altering the potential that is applied to an electrode causes the charge on the metal side of the interface to change and some reorganization of the ions and solvent dipoles in the double layer on the solution side of the interface will occur. This process causes electrons to flow into or out of the surface giving rise to the charging or capacitive response. The double layer capacitance for a disc-shaped ultramicroelectrode is proportional to the area of the electrode surface and is given by Equation (2),

$$C = \pi r^2 C_o$$

where $C_o$ is the specific double layer capacitance of the electrode. Thus, shrinking the size of the electrode causes the interfacial capacitance to decrease with decreasing $r^2$.

The existence of the double layer capacitance at the working electrode complicates electrochemical measurements at short timescales. Figure 2 is an equivalent circuit of an electrochemical cell, where $Z_f$ is the Faradaic impedance corresponding to the electrochemical reaction. In seeking to make transient measurements, the electrochemical cell must respond to the applied potential waveform much more rapidly than the process one is seeking to measure. However, the potential across a capacitor cannot be changed instantaneously and the double layer capacitance must be charged through the solution resistance in order to change the potential across the Faradaic impedance.

The time constant for this charging process is given by Equation (3):

$$RC = \frac{\pi r C_o}{4\kappa}$$

and is typically hundreds of microseconds for a conventional millimeter-size electrode, placing a lower limit on the useful timescale of the order of several milliseconds. The use of ultramicroelectrodes with critical dimensions in the micrometer and even nanometer range has opened new possibilities for fast kinetic studies because of the greatly diminished capacitance of these ultrasmall probes.

For example, Figure 3 shows how the $RC$ cell time constant as measured in 0.1 M HCl depends on the radius of platinum microdisc electrodes. In these experiments, the double layer charging process was monitored using chronoamperometry conducted at microsecond timescales following a potential step within the double layer region of the voltammogram. As the electrode radius decreases from 25 to 1 $\mu$m, the cell time constant decreases linearly from approximately 2 $\mu$s to 80 ns. The slope of the best fit line is consistent with Equation (3) where the double layer capacitance is about 40 $\mu$F cm$^{-2}$. Moreover, the intercept is approximately 4.3 ns indicating that the stray capacitance (see below) of these microelectrodes is very small. In conclusion, it is apparent that by using ultramicroelectrodes with radii of microns, cell time constants of tens of nanoseconds can be achieved.

![Figure 2](image2.png)

**Figure 2** Equivalent circuit for an electrochemical cell and associated electrochemical process.

![Figure 3](image3.png)

**Figure 3** Relationship between the $RC$ cell time constant and the radius of platinum microdiscs where the supporting electrolyte is 0.1 M HCl. Cell time constants were measured using chronoamperometry conducted on a microsecond to submicrosecond timescale by stepping the potential from 0.200 to 0.250 V vs Ag/AgCl.
The preceding analysis indicates that the overall cell resistance influences the cell time constant. Therefore, decreasing the resistance of the solution, through which the Faradaic and charging currents must flow, will decrease the cell time constant. Figure 4 illustrates the decrease in cell time constant that is observed for a 5 µm radius platinum microdisc as the solution conductivity is systematically varied by changing the supporting electrolyte concentration from 0.05 to 2.0 M. As predicted by Equation (3), this figure shows that a linear response is obtained, and the specific double layer capacitance is estimated as 41.7 ± 2.1 µF cm⁻² over this range of supporting electrolyte concentrations. Significantly, Figures 3 and 4 indicate that microdisc electrodes can be manufactured that respond ideally to changes in the applied potential at timescales as short as 30 ns. Experiments performed in more conducting solutions, e.g. highly concentrated acids, indicate that RC cell time constants as short as 5 ns can be achieved.

However, there are a number of practical problems associated with the design and fabrication of microelectrodes that cause micrometer-sized electrodes to have RC time constants that greatly exceed those predicted by Equation (3).

An important cause of nonideal responses is stray capacitance within the electrochemical system that may arise from the electrode itself, the leads, or electrical connections. Stray capacitance will increase the cell time constant as described by Equation (4).

\[
RC = \frac{1}{4\pi r} \left( \pi r^2 C_0 + C_{\text{Stray}} \right)
\]  

where \( C_{\text{Stray}} \) is the stray capacitance. Although it depends on the microelectrode design and the experimental setup, this stray capacitance is typically between a few picofarads and several tens of picofarads. The cell time constant observed in these circumstances depends strongly on the relative magnitudes of the double layer and stray capacitances. At a normal size electrode, the stray capacitance is negligible compared to the double layer capacitance and therefore does not significantly affect the observed cell time constant. However, when the magnitude of the double layer capacitance is reduced by shrinking the size of the electrode to micrometer and submicrometer dimensions, the stray and double layer capacitances can become comparable. For example, taking a typical value of 40 µF cm⁻² as the specific double layer capacitance for a platinum electrode in contact with 1 M aqueous electrolyte solution, the double layer capacitance of a 1 µm radius disc will be approximately 1 µF. This value is significantly larger than the picofarads stray capacitance found in a typical electrochemical experiment. However, for a 1 µm radius microdisc, the interfacial capacitance will decrease by six orders of magnitude to approximately 1 picofarad. Therefore, stray capacitance of even a few picofarads will cause the observed RC time constant to increase significantly beyond the minimum value dictated by double layer charging alone. This increased cell time constant will cause the transient response characteristics of the electrodes to become nonideal. Thus, an important objective in seeking to implement ultrafast transient techniques is to minimize the stray capacitance.

There are two major sources of stray capacitance. First, the capacitance of the cell leads and capacitive coupling between leads. Second, the microelectrode itself. By using high-quality cable of minimum length, e.g. by mounting the current-to-voltage converter directly over the electrochemical cell, and by avoiding the use of switches as far as possible, stray capacitance from the electrochemical system can be minimized. However, the importance of good microelectrode fabrication and design should not be overlooked. For example, if there is a small imperfection in the seal between the insulator and the electrode material then solution leakage will cause the RC cell time constant to increase massively and the Faradaic response may become obscured by charging/discharging processes. Moreover, as shown by Wightman’s group and Faulkner et al., using silver epoxy or mercury to make the electrical connection between the microwire and a larger hook-up wire can cause the RC cell time constant to increase dramatically. This increase arises because the electronically conducting mercury/glass insulator/ionically conducting solution junctions cause significant stray capacitance. It is important to note that
these effects may only become apparent in high-frequency measurements.

2.3 Ohmic Effects
When Faradaic and charging currents flow through a solution, they generate a potential that acts to weaken the applied potential by an amount \( iR \), where \( i \) is the total current. This is an undesirable process that leads to distorted voltammetric responses. It is important to note that, as described by Equation (1), microelectrodes exhibit higher resistances than macroelectrodes because of their smaller size. However, the currents observed at microelectrodes are typically six orders of magnitude smaller than those observed at macroelectrodes. These small currents often completely eliminate ohmic drop effects even when working in organic solvents. For example, the steady-state current observed at a 5 \( \mu \)m radius microdisc is approximately 2 nA for a 1.0 mM solution of ferrocene. Taking a reasonable value of 0.01 \( \Omega^{-1} \text{cm}^{-1} \) as the specific conductivity, then Equation (1) indicates that the resistance will be of the order of 50 000 \( \Omega \). This analysis suggests that the \( iR \) drop in this organic solvent is a negligible 0.09 mV. In contrast, for a conventional macroelectrode the \( iR \) drop would be of the order of 5–10 mV. Under these circumstances, distorted current responses and shifted peak potentials would be observed in cyclic voltammetry.

It is useful at this point to investigate the effect of experimental timescale on the \( iR \) drop observed at microelectrodes. The following section discusses the way that the diffusion field at microelectrodes depends on the characteristic time of the experiment. However, in general, at short times, the dominant mass transport mechanism is planar diffusion and the microelectrode behaves like a macroelectrode. Therefore, at short times the current \( i \) decreases with decreasing electrode area (\( r^2 \)). Since the resistance increases with decreasing electrode radius rather than electrode area, the product \( iR \) decreases with decreasing electrode radius in short timescale experiments. Thus, beyond the reduced \( iR \) drop because of low currents, decreasing the electrode radius from say 1 mm to 10 \( \mu \)m decreases the ohmic \( iR \) drop observed at short times by a factor of one hundred. In contrast, at long experimental timescales the Faradaic current depends directly on the radius making the product \( iR \) independent of the electrode radius. Thus, while the low currents observed at microelectrodes reduce ohmic effects for all experimental timescales, using the transient rather than the long timescale response offers even better performance.

2.4 Mass Transport
Oxidation or reduction of a redox-active species at an electrode surface generates a concentration gradient between the interface and the bulk solution. This redox process requires electron transfer across the electrode/solution interface. The rate at which electron transfer takes place across the interface is described by the heterogeneous electron transfer rate constant, \( k \). If this rate constant is large, then diffusional mass transport will control the current observed. Our objective is to describe how these diffusional fields evolve in time. The experiment of interest involves stepping the potential from an initial value where no electrode reaction occurs, to one where electrolysis proceeds at a diffusion controlled rate. Consider the case of a spherical electrode of radius \( r_s \) placed in a solution that contains only supporting electrolyte and a redox-active species of concentration \( C \). The concentration gradient at the electrode surface is obtained by solving Fick’s second law in spherical coordinates, Equation (5)

\[
\frac{\partial C(r, t)}{\partial t} = D \frac{\partial^2 C(r, t)}{\partial r^2} + \frac{2}{r} \frac{\partial C(r, t)}{\partial r}
\]

The boundary conditions for the potential step experiments described above are shown in Equation (6)

\[
\lim_{t \to \infty} C(r, t) = C^\infty \\
C(r, 0) = C^\infty \\
C(r, t) = 0 \quad \text{for } t > 0
\]

where \( r \) is the distance from the center of the sphere, \( D \) is the diffusion coefficient for the redox active species, and \( C \) is the concentration as a function of distance \( r \) and time \( t \).

Equation (5) can be solved using Laplace transform techniques to give the time evolution of the current, \( i(t) \), subject to the boundary conditions described. Equation (7)

\[
i(t) = \frac{nFADC^\infty}{r_s} + \frac{nFAD^{1/2}C^\infty}{\pi^{1/2}t^{1/2}}
\]

is obtained where \( n \) is the number of electrons transferred in the redox reaction, \( F \) is Faraday’s constant, and \( A \) is the geometric electrode area.

Equation (7) shows that the current response following a potential step contains both time-independent and time-dependent terms. The differences in the electrochemical responses observed at macroscopic and microscopic electrodes arise because of the relative importance of these terms at conventional electrochemical timescales. It is possible to distinguish two limiting regimes depending on whether the experimental timescale is short or long.
The current attains a time-independent steady-state value given by Equation (9)

\[ i_{ss} = \frac{nFADC^\infty}{r_s} \]  

(9)

The steady-state response arises because the electrolysis rate is equal to the rate at which molecules diffuse to the electrode surface.

Since short and long times are relative terms, it is useful to determine the times over which transient and steady-state behaviors will predominate and

Figure 6 shows the relationship that exists between the range of useable scan rates and electrode radius subject to the condition that ohmic drop is negligible and that the dominant mass transport regime is linear diffusion.\(^8\)

2.4.2 Long Times

At long times, the transient contribution given by the second term of Equation (7) has decayed to the point where its contribution to the overall current is negligible. At these long times, the spherical character of the electrode becomes important and the mass transport process is dominated by radial (spherical) diffusion as illustrated in Figure 5(b).

The theoretical limitations to ultrafast cyclic voltammetry. The shaded (or cross-hatched) area between the slanted lines represents the radius that a microdisc must have if the ohmic drop is to be less than 15 mV and distortions due to nonplanar diffusion account for less than 10% of the peak current. (a) Without iR drop compensation by positive feedback; (b) with 90% and 99% ohmic drop compensation. The dotted areas in (a) and (b) represent the regions where transport within the double layer affects the voltammetric response. Limits are indicative and correspond approximately to a 5-mM anthracene solution in acetonitrile, with 0.3-M tetrafluoroborate as supporting electrolyte. (Reprinted from C. Amatore, Electrochemistry at Microelectrodes, ed. I. Rubenstein, Chapter 4, 1995 by courtesy of Marcel Dekker, Inc.)

Figure 5 Diffusion fields observed at microelectrodes. (a) Linear diffusion observed at short times. (b) Radial (convergent) diffusion observed at long times.

2.4.1 Short Times

At sufficiently short times, the thickness of the diffusion layer that is depleted of reactant is much smaller than the electrode radius and the spherical electrode appears to be planar to a molecule at the edge of this diffusion layer. Under these conditions, the electrode behaves like a macroelectrode and mass transport is dominated by linear diffusion to the electrode surface as illustrated in Figure 5(a). At these short times, the \( t^{-1/2} \) dependence of the second term in Equation (7) makes it significantly larger than the first term and the current response induced by the potential step initially decays in time according the Cottrell equation, Equation (8)

\[ i(t) = \frac{nFAD^{1/2}C^\infty}{\pi^{1/2}t^{1/2}} \]  

(8)

how this time regime is affected by the electrode radius.

This objective can be achieved by considering the ratio of the transient to steady-state current contributions (Equations (8) and (9), respectively). This analysis gives a dimensionless parameter \( \frac{\pi D t}{r_s^2} \), that can be used to calculate a lower time limit at which the steady-state contribution will dominate the total current to a specified extent. For example, the time required for the steady-state current contribution, \( i_{ss} \), to be ten times larger than the transient component, \( i_t \), can be calculated. Taking a typical value of \( D \) as \( 1 \times 10^{-5} \text{ cm}^2 \text{s}^{-1} \) for an aqueous solution, then for an electrode of radius 5 mm, the experimental timescale must be longer than 80 s. Therefore, steady state is not observed for macroelectrodes at the tens of millivolts per second timescale typical of conventional cyclic voltammetry experiments. However, reducing the electrode radius by a factor of a thousand to 5 \( \mu \)m, means that a steady-state response can be observed for times longer than 80 \( \mu \)s. Since the steady-state current becomes more dominant with increasing time, steady-state responses are easily observed for microelectrodes in electrochemical experiments run at conventional timescales. Figure 7(a) shows the sigmoidal-shaped responses that characterize steady-state mass transfer in slow scan rate cyclic voltammetry. In contrast, at short experimental timescales (high scan rates) peaked responses (Figure 7b) similar to those observed at conventional macroelectrodes are seen.

The preceding analysis considered a spherical electrode because its surface is uniformly accessible and a simple closed-form solution to the diffusion equation exists. The microdisc is the most widely used geometry, but derivation of rigorous expressions describing their experimental response is complicated because the surface is not uniformly accessible. For discs, electrolysis at the outer circumference of the disc diminishes the flux of the electroactive material to the center of the electrode. However, microdisc and microring geometries share the advantage of spherical microelectrodes in that quasi-spherical diffusion fields are established in relatively short periods of time. The steady-state current for a disc is given by Equation (10)

\[
i_{ss} = 4nFDCr,
\]

where \( r \) is the radius of the disc.

Observing a steady-state response depends on all the electrode dimensions being small, not just the radius, and is therefore not achieved for every geometry at the timescales considered above. For example, band electrodes whose thickness is in the micrometer range, but whose length is several millimeters, do not exhibit true steady-state responses. However, a high analyte flux to the ends of the band often makes it possible to observe a pseudo-steady-state condition in a practical sense.

Radial diffusion gives very high rates of mass transport to the electrode surface with a mass transport coefficient of the order of \( D/r \). Therefore, even at rotation rates of \( 10^4 \text{ rpm} \), convective transport to a rotating macroelectrode is smaller than diffusion to a 1 \( \mu \)m microdisc. The high flux at a microelectrode means that a reverse wave under steady-state conditions is not observed (Figure 5a), because the electrolysis product leaves the diffusion layer at an enhanced rate.

### 2.5 Instrumental Challenges

Taking typical values of 1 mM and \( 1 \times 10^{-5} \text{ cm}^2 \text{s}^{-1} \) for the concentration and diffusion coefficient, respectively, the steady-state current is of the order of 2 nA for a 5 \( \mu \)m radius microdisc. As described by Equation (10), the magnitude of this current will decrease with decreasing electrode radius and picoamp currents will be observed for a 10 nm radius electrode. These are certainly small currents but can be measured with relatively simple circuits based on operational amplifiers. This success can only be achieved because the measurement is performed at long timescales.
In contrast, trying to measure the currents generated at microelectrodes at short timescales poses real technological challenges. The current observed at short timescales is typically in the microamp range. For example, when the potential is stepped to a value where electrolysis proceeds at a diffusion-controlled rate, the Faradaic current observed 1 µs after the application of the potential step will be approximately 135 nA for a 5 µm radius microdisc, i.e. almost two orders of magnitude larger than the steady-state value. However, there is a difficulty in using operational amplifiers to measure these short timescale currents. For a given operational amplifier, the product of the gain and frequency bandwidth is a constant. Therefore, if a large amplification of a small current is required then the time resolution will be adversely affected and it will become increasingly more difficult to probe fast electron transfer dynamics accurately. The development of faster electronic components, notably for the capture, processing, and streaming of video images, will certainly continue to decrease the lower accessible limit. However, even today, measuring submicroamp currents with nanosecond time resolution remains a significant technological challenge.

Another approach to solving this amplification problem is to use microelectrode arrays. Arrays are ensembles of microelectrodes that may consist of regularly or irregularly spaced assemblies of identical electrodes, ensembles of electrodes with identical shape but uneven dimensions, or disordered arrangements of irregularly shaped electrodes. In seeking to make ultrafast measurements, the advantage of using a microelectrode array is that it provides a nonelectronic approach to current amplification. Often the individual elements are not independently addressable and all of the electrodes operate at the same applied potential. Under these conditions, the total response of the array depends on the relative size of the individual electrodes and the thickness of the diffusion layer that develops around each element during electrolysis. When seeking to make ultrafast measurements, the individual diffusion fields need to act independently of one another, i.e. the separation of the electrodes must be much larger than the diffusion layer thickness throughout the experiment. If the diffusion layers that develop at the individual electrodes merge, then a planar diffusion layer is created that extends over the entire surface of the array. Under these conditions, the array behaves like a large electrode whose surface area is given by the sum of the electrochemically active and inactive areas. This condition does not yield any benefit in terms of probing fast electron transfer dynamics.

Thus, arrays used for dynamic measurements typically consist of N widely separated and noninteracting discs that will provide N times the current observed at a single electrode. In terms of the RC cell time constant, such a microelectrode array can be considered as a circuit of N parallel combinations of each single microelectrode. Thus, the equivalent resistance and capacitance are $R/N$ and $N \times C$, respectively. The product, $RC$, of the array remains unchanged from that found at a single element of the assembly. Microelectrode arrays appear to offer the same advantages as a single microelectrode, but it is not necessary to construct such a high-gain current-to-voltage converter, making measurements at shorter timescales possible. However, in the short timescale limit (nonoverlapping diffusion fields), the gain achieved is necessarily finite and fixed by the total number of microelectrodes in the array. In this sense, the amplification achieved is less flexible and of lower quality than is possible using electronic means. Moreover, fabrication of microelectrode arrays with electrode radii smaller than ten micrometers, in which each electrode exhibits its theoretical RC time constant, remains technologically challenging.

### 2.6 Transient Techniques

In transient electrochemical measurements involving a solution-phase redox couple, one seeks to create a competition between the reaction of interest, electron transfer at the electrode surface or coupled homogeneous steps, and diffusion of the species to and from the electrode surface. In the following sections, consideration is given to how high diffusion rates that allow fast reactions to be investigated are obtained by controlling the experimental timescale directly, i.e. by applying a shorter and shorter time perturbation to the system.

In order to extract useful kinetic information from transient electrochemical responses, the Faradaic and charging currents must be separated. This requirement presents a number of challenges when attempting to perform experiments at very short timescales. For example, in fast scan rate cyclic voltammetry, the charging current increases proportionally to the scan rate while the Faradaic current for diffusive species is proportional to the square root of the scan rate. These dependencies cause the ratio of the Faradaic to charging current ratio to decrease with increasing scan rate. In some sense, this process corresponds to a decreasing signal-to-noise ratio since the magnitude of the charging current places a lower limit on the detectable Faradaic current. One strategy for dealing with capacitive charging is to use high frequency experiments. However, this approach is limited since at high scan rates the magnitudes of the charging and Faradaic currents are often similar.

While microelectrodes can significantly decrease the deleterious effects of ohmic drop, the large currents...
observed in short-timescale transient experiments can result in significant $iR$ drop and distorted voltammograms. Determination of heterogeneous electron transfer rate constants often relies on measuring the scan rate dependence of the peak-to-peak separation, $\Delta E_P$. Ohmic effects represent a serious problem, not only because they will cause a significant $\Delta E_P$ to be observed even when heterogeneous electron transfer is fast, but also because the magnitude of the ohmic effect depends on the experimental timescale. Several strategies have been used to decrease ohmic effects. First, the Faradaic information is extracted by means of convolution of the voltammograms with the diffusion operator $(\pi t)^{-1/2}$. Second, the experimental voltammogram is simulated using a model that incorporates ohmic and capacitive factors. Third, corrections for ohmic drop are made online, using positive feedback circuitry. Savéant et al.\(^{(11)}\) have developed high-speed potentiostats capable of providing positive feedback to compensate on-line for ohmic drop at scan rates up to $5 \times 10^5 \text{ V s}^{-1}$.

In contrast to cyclic voltammetry, for chronoamperometric experiments the decay rates for double layer charging and Faradaic processes are different, allowing the two processes to be separated on a kinetic basis. Ideally, the double charging current undergoes a single exponential in time while the Faradaic current for a diffusional species decreases with the square root of time. Therefore, at short times the current will be dominated by the charging current while at long times the diffusion controlled Faradaic current will be relatively more significant.

2.6.1 Heterogeneous Electron Transfer Dynamics

As discussed above, at short times the diffusion layer thickness is much smaller than the microelectrode radius and the dominant mass transport mechanism is planar diffusion. As observed for macroelectrodes at conventional millivolt per second scan rates, the Faradaic current increases in proportion to the electrode area. Under these conditions, the classical theories, e.g. that of Nicholson and Shain,\(^{(12)}\) can be used to extract kinetic parameters from the scan rate dependence of the separation between the anodic and cathodic peak potentials. The peak-to-peak separation increases with increasing scan rate thus improving the accuracy of the rate constant determination. However, as discussed above, stray capacitance, ohmic drop, double layer charging currents, and difficulties posed by bandwidth limitations of the instrument must be recognized. These effects can be recognized by performing measurements across the whole dynamic range available, i.e. from kilovolts per second to megavolts per second.

As shown in Table 1, the heterogeneous electron transfer dynamics of a diverse range of organic and inorganic species have been investigated using transient techniques. However, cyclic voltammetry of the anthracene/anthracene anion radical has been used extensively as a reference system for characterizing new electrodes or instruments. This focus arises because the aromatic nature of the molecule leads to very small changes in the bond lengths and angles, i.e. the Marcus inner sphere reorganization energy is small,\(^{(13)}\) causing the heterogeneous electron transfer rate constant to be large. Howell and Wightman\(^{(14)}\) have studied this reaction using cyclic voltammetry at scan rates up to $10^5 \text{ V s}^{-1}$ and good agreement between the predictions of the Nicholson and Shain theory and experiment was found after correcting for the nonspherical nature of the microdisc used.

A useful strategy in trying to extend the upper limit of measurable electron transfer rate constants is to perform measurements at lower temperatures. This strategy is successful because even for heterogeneous electron transfers with negligible inner sphere reorganization energies, activation barriers of the order of 20–25 kJ mol$^{-1}$ are expected. Therefore, considerably slower rates of heterogeneous electron transfer ought to be observed even by decreasing the temperature of the electrochemical cell by a few tens of degrees. Measurements of this type are facilitated greatly by microelectrodes, since solvents, such as alcohols or nitriles that remain liquid over a wide temperature range, can be used without catastrophic ohmic effects. For example, Weaver and coworkers investigated the ferrocene, $o$-nitrotoluene, and nitromesitylene systems in acetonitrile, propionitrile, and butyronitrile at a gold microdisc using scan rates up to $10^4 \text{ V s}^{-1}$ between 200 and 300 K.\(^{(15)}\) The experimental voltammograms were interpreted with the aid of simulated responses that accounted for the activation enthalpy, temperature-dependent diffusion coefficients, and double layer capacitance. For ferrocene, the standard heterogeneous electron transfer rate constants ranged from 0.083 cm s$^{-1}$ at 198 K to approximately 5.5 cm s$^{-1}$ at 298 K yielding an activation enthalpy of 20 kJ mol$^{-1}$.

There is little doubt that temperature-dependent studies offer a useful new insight into the electrochemical behavior of fast redox couples especially by providing activation enthalpies, entropies, and reaction free energies that allow electronic coupling terms to be evaluated. However, as exemplified by the careful work of Evans et al.\(^{(12)}\) and Safford and Weaver,\(^{(15)}\) attention must be paid to two important processes. First, the rate of diffusional mass transport will decrease with decreasing temperature. This process will make the voltammetric response less sensitive to the electrode kinetics. Second, lower temperatures will cause the solution resistance to increase, which can cause an enhanced peak-to-peak separation to be observed that could be incorrectly interpreted as slow heterogeneous electron transfer.

\(^a\) Dimension given is the radius of a microdisc electrode unless otherwise stated.

Irrespective of whether steady-state or transient approaches are used, the electrode surface activation, pretreatment, roughness, degree of sample adsorption, and electrode material as well as the nature and concentration of the supporting electrolyte, sample concentration, and solvent type and purity, can have a profound effect on the magnitude of the heterogeneous electron transfer rate observed.

Despite the many elegant investigations that have been conducted into heterogeneous electron transfer dynamics using ultrafast electrochemical techniques, the magnitude of the diffusion-controlled current at short times ultimately places a lower limit on the accessible timescale. For diffusive species, the thickness of the diffusion layer, \(\delta\), is defined as \(\delta = (\pi D t)^{1/2}\) and is therefore proportional to the square root of the polarization time, \(t\). The diffusion layer thickness can be estimated to be approximately 50 Å if the diffusion coefficient is \(1 \times 10^{-5}\) cm\(^2\) s\(^{-1}\) and the polarization time is 10 ns. Given a typical bulk concentration of the electroactive species of 1 mM, this analysis reveals that only 10000 molecules would be oxidized or reduced at a 1 µm radius microdisc under these conditions. The average current for this experiment is only 170 nA, which is too small to be detected with low-nanosecond time resolution.

Therefore, in order to probe the dynamics and energetics of ultrafast heterogeneous electron transfer dynamics this diffusion limitation must be eliminated. One successful approach to achieving this objective is to use self-assembled or spontaneously adsorbed monolayers. When immobilized on an electrode surface the electroactive species no longer needs to diffuse to the electrode to undergo electron transfer. Moreover, the electroactive species is preconcentrated on the electrode surface. For example, in the situation considered above, there will be approximately \(1.7 \times 10^{-20}\) mol of electroactive material within the diffusion layer. Given that the area of a 1 µm disc is approximately \(3.1 \times 10^{-8}\) cm\(^2\), this translates into an “equivalent surface coverage” of about \(5.4 \times 10^{-13}\) mol cm\(^{-2}\). In contrast, the surface coverage, \(\Gamma\), observed for dense monolayers of adsorbates is typically more than two orders of magnitude larger with coverages of the order of \(10^{-10}\) mol cm\(^{-2}\) being observed. This higher concentration gives rise to much larger currents that are easier to detect at short timescales.
For example, Faulkner et al. have investigated the dynamics and energetics of electron transfer across mercury/anthraquinone monolayer interfaces. The surface coverage of an anthraquinone-2,6-disulfonic acid (2,6-AQDS) monolayer formed from a solution containing micromolar concentrations of the quinone was approximately 1.6 x 10^{-10} mol cm^{-2}. Therefore, in transient electrochemical experiments performed on nanosecond timescales, the average Faradaic current would be expected to be of the order of 50 µA. It is technologically feasible to detect currents of this magnitude with circuitry based on existing wide bandwidth operational amplifiers.

As exemplified by the work of Chidsey, Forster and Faulkner, electroactive adsorbed monolayers have been developed that exhibit close to ideal reversible electrochemical behavior under a wide variety of experimental conditions of timescale, temperature, solvent and electrolyte. In order for a monolayer to be an attractive model system for understanding those factors that control the rate of heterogeneous electron transfer, it should have a number of properties. The nature and physical location of the electroactive center within the molecule should be well defined. The electron transfer should be mechanistically simple with the electrochemical responses being close to ideally reversible and stable over prolonged periods. The molecules should adsorb strongly onto electrode surfaces in both oxidized and reduced forms. It should be possible to control the surface coverage by controlling the concentration of the adsorbate in solution (reversible physisorption), by controlling the time that the pristine electrode is exposed to the deposition solution, by using electroinactive diluents, or by controlled desorption from a high-coverage monolayer. The layers should be stable in a wide variety of solvents, especially water, to allow the effect of solvent parameters, e.g. relaxation rate and dielectric constant, on simple electron transfer processes to be investigated.

In these respects, monolayers containing ferrocene or ruthenium hexamine are attractive model systems for studying heterogeneous electron transfer across electrode/monolayer interfaces. However, in many of these studies the bridging ligand linking the electroactive group to the electrode surface has been carefully chosen with regard to its length and electronic structure so that electron transfer occurs on a millisecond or longer timescale. Therefore, ultrafast electrochemical techniques are not required to probe the details of electron transfer. In contrast, species that are directly adsorbed onto the electrode surface (e.g. anthraquinones) or where the bridging ligand is shorter (e.g. 4,4’-dipryridyl-type linkers) can undergo electron transfer on the submicrosecond timescale. For example, Faulkner et al. found that 2,6-AQDS monolayers can be reversibly converted to the hydroquinone form in a two-electron, two-proton mechanism and virtually ideal cyclic voltammetry and chronoamperometry are observed. The standard heterogeneous electron transfer rate constant is in the range of 10^4 to 10^5 s^{-1} depending on the driving force (overpotential, n \equiv E_{app} - E^0) for the reaction and the proton concentration.

Acevedo and Abruna formed spontaneously adsorbed monolayers of the complex [Os(bpy)_2 Cl (dipy)]^+, where dipy is 4,4’-trimethylenedipyridine, and investigated their dynamic and energetic properties. The voltammetric responses observed for the Os^{2+/3+} redox reaction at scan rates over 8000 V s^{-1} were close to the behavior expected for an ideal reversible one-electron transfer reaction involving a surface-confined species. They used Laviron’s formalism describing the variation of the peak potential with scan rate to estimate the rate of heterogeneous electron transfer as 2 x 10^5 s^{-1}.

The formation and structure of these monolayers on Pt(111) surfaces was investigated using scanning tunneling microscopy (STM) and electrochemical scanning tunneling microscopy (ECSTM). Molecularly resolved images were obtained that demonstrated that the monolayer exists as a tightly packed two-dimensional crystal on the electrode surface. Abruna also demonstrated that the exchange dynamics associated with the desorption and displacement of these adsorbates are controlled by the rate of desorption via a dissociative mechanism and that the applied potential does not significantly affect the free energy of adsorption.

The ideality of the electrochemical response exhibited by these osmium-containing monolayers makes them attractive model systems for probing the effect of solvent, electrolyte, and temperature on the electron transfer dynamics. Faulkner and Forster investigated these effects for [Os(bpy)_2 Cl (pNp)]^+, where pNp is 4,4’-dipryld, 1,2-bis(4-pyridyl)ethane, or dipy, monolayers on platinum microelectrodes. The rate of heterogeneous electron transfer was measured using chronoamperometry conducted on a low microsecond timescale.

For the Os^{2+/3+} redox reaction, heterogeneous electron transfer is a rapid first-order process characterized by a single unimolecular rate constant (k/s^{-1}). Tafel plots of the dependence of ln k on the electrochemical driving force (overpotential) show curvature, indicating that the transfer coefficient is potential-dependent. For sufficiently large overpotentials, k tends to become independent of the free energy driving force, which is consistent with Marcus theory. The response is asymmetric with respect to overpotential, with the slope for the oxidation process tending towards zero more rapidly than that for the reduction process. This response was modeled as a tunneling process between electronic manifolds on the two sides of the interface. Temperature-resolved measurements of k and the formal potential were made.
from $-5$ to $+40{\degree}C$ to provide enthalpies and entropies of activation, respectively. The corresponding free energies of activation ranged from 12.3 kJ mol$^{-1}$ in acetonitrile to 6.4 kJ mol$^{-1}$ in chloroform. There is weak coupling between the electronic manifolds on the two sides of the electrochemical interface. Surprisingly however, $k$ depends linearly on the longitudinal relaxation rate of the solvent. This behavior is not predicted on the basis of contemporary theories of electron transfer. These Os- and related ruthenium-containing monolayers have been used to investigate interfacial field effects on reductive chloride elimination and as model systems for investigating how Faradaic responses that occur at identical formal potentials can be separated on a kinetic basis.\(^{39}\)

More recently, Forster has probed the dynamics of both metal-centered oxidation and ligand-based reduction processes to address how electronic states of the bridging ligand contribute to the electron tunneling pathway.\(^{40}\) This work indicates that the close proximity of the redox potentials of the bridge and the remote bipyridyl ligands leads to stronger electronic coupling between the electrode and bipyridyl ligands than between the electrode and the osmium center. Forster and O’Kelly also investigated monolayers that incorporated a ligand capable of undergoing protonation/deprotonation reactions within the coordination shell of the metal center.\(^{41}\) This study showed that the rate of heterogeneous electron transfer across the metal/monolayer interface depends on the pH of the contacting electrolyte. From a molecular electronics perspective, pH-induced conformational gating of this type offers the possibility of developing pH-triggered electrical switches.

There are few literature reports addressing the issue of separating charging and Faradaic currents in chronamperometric experiments involving surface-confined reactants. Separating these contributions is complicated by the fact that both are expected to exhibit single exponential decays in time. Measuring the capacitive response in blank supporting electrolyte is not a useful strategy since the double-layer capacitance is altered by adsorption. Moreover, the interfacial capacitance depends on the redox composition of the monolayer. Much of the work discussed above relies on a kinetic separation of these currents, i.e. a microelectrode with an $RC$ cell time constant at least five times smaller than the redox process under investigation is used causing the short and long timescale currents to be dominated by double-layer charging and the Faradaic reactions, respectively. However, approaches based on digital simulation and Laplace transform methods have been developed.\(^{42}\)

2.6.2 Homogeneous Chemical Kinetics

There are two important advantages in using micro-rather than macroelectrodes for probing the dynamics of homogeneous chemical reactions. First, because of their relative immunity to ohmic effects, microelectrodes have greatly extended the range of useful media, e.g. low-dielectric-constant solvents, solids, and solutions with no deliberately added electrolyte. This capability often makes it feasible to compare electrochemical rate constants directly with those obtained using other techniques, notably transient absorption or luminescence spectroscopy. Second, very high diffusion rates and high-quality data can be obtained at short experimental timescales. These decreases in the lower accessible time limit have important implications for probing the dynamics of rapid heterogeneous electron transfer and homogeneous chemical reactions alike. For example, bimolecular reactions in solution cannot proceed faster than the rate at which molecules come into close contact. Thus, bimolecular rate constants cannot exceed the diffusion-limited rate constant that is of the order of $10^9 - 10^{10}$ M$^{-1}$ s$^{-1}$ in most organic solvents. Since the characteristic time of cyclic voltammetry is $RT/Fv$, where $v$ is the scan rate, experiments performed at mV s$^{-1}$ scan rates allow kinetic information, such as lifetimes that are close to the diffusion limit, to be obtained.\(^{43}\)

In the past, when the rate constant for the following reaction was large, the voltammetric response was irreversible because the intermediate underwent a following chemical reaction before the direction of the potential scan was reversed. With the development of microelectrodes and high-scan-rate voltammetry, it is now possible to detect the fast-decaying intermediate. In many circumstances, it is even possible to observe reversible electrochemical responses since the experimental timescale can be made shorter than the lifetime of the electrogenerated reactant. For example, as illustrated in Figure 8, Howell and Wightman\(^{44}\) have shown that the irreversible response observed for the oxidation of anthracene at slow scan rates becomes fully reversible at a scan rate of 10$^4$ V s$^{-1}$. This behavior is opposite to that expected when heterogeneous electron transfer is slow and suggests that the cation radical undergoes a following chemical reaction. The ability to make the voltammetric response reversible means that the formal potentials of highly reactive species can be measured accurately. However, it is important that ohmic drop is negligible, or is made so using on-line current interrupt or positive feedback approaches, otherwise the experimental responses have to be modeled if true thermodynamic information is to be obtained.

Beyond this thermodynamic information, transient measurements can be used to probe the mechanism of the following chemical reaction. For example, the oxidation of anthracene has been reported widely as proceeding through an ECE mechanism, where E denotes an electron transfer step and C a chemical reaction. However,
Figure 8 Effect of scan rate on the voltammetric response observed at a 5-µm platinum microdisc for the oxidation of 2.36-mM anthracene in dimethylformamide (DMF) containing 0.6-M tetraethyl ammonium perchlorate. (Reprinted with permission from J.O. Howell and R.M. Wightman, J. Phys. Chem., 88, 3915. Copyright (1984) American Chemical Society.)

Osteryoung et al.\textsuperscript{45} report that closer agreement is found between staircase, square wave, normal pulse, and reverse pulse responses and a DISP1 mechanism, where DISP denotes a disproportionation (DISP) reaction. First-order rate constants range from 3×10\(^{-7}\) to 500 s\(^{-1}\). However, for true first-order kinetics, the same rate constant ought to be obtained irrespective of the time at which the transient response is analyzed. In the case of anthracene oxidation, smaller rate constants are observed at long times. This behavior may arise because of low concentrations of reactive impurities in the sample that compete with the main reaction at long times.

As indicated in Table 2, the kinetics of many following chemical reactions have been investigated using transient methods at microelectrodes including the oxidation of polyalkylbenzenes, anthracene, aromatic hydrocarbons, and ascorbic acid; the reduction of quinones, aryl halides, chloroquinoline, acetophenones, and butylpyridinium derivatives; and the initial stages of electropolymerization of the conducting polymer polypyrrole. The shortest lifetime attainable is currently in the tens of nanoseconds range, e.g. the lifetime for reductive dimerization of the 2,6-diphenylpyrillium cation in acetonitrile has been determined to be 50 ns.\textsuperscript{43}

The ability of individual solvents to stabilize transition states can have a profound effect on the observed rate constants. For example, Wipf and Wightman\textsuperscript{52} studied the cleavage reaction involved in the reduction of 9-chloroanthracene in low dielectric solvents including tetrahydrofuran, dichloromethane, and chlorobenzene. These measurements would simply be impossible using conventional macroelectrodes. The transition state in this reduction involves transfer of the negative charge of the anion radical to the chlorine atom. The localized negative charge can be stabilized by the solvent thus lowering the energy of the transition state and yielding a more rapid cleavage. Measurements of this type not only provide fundamental mechanistic information but also play an important role in seeking to optimize industrial processes.

\(^a\) Dimension given is the radius of a microdisc electrode unless otherwise stated.
Bond formation is also amenable to investigation using ultrafast transient electrochemical techniques. For example, dimerization reactions triggered by electron transfer have been investigated using both cyclic voltammetry and potential-step methods. Andrieux, Hapiot, and Savéant have made seminal contributions in this area. For example, using chronoamperometry conducted on a microsecond timescale, these authors showed that reduction of 1-methyl-4-tert-butylpyridinium cations in DMF leads to radical–radical coupling at a rate of $6.4 \pm 0.4 \times 10^6 \text{M}^{-1} \text{s}^{-1}$. Their method of analysis involves stepping the potential to a value that is sufficiently negative of the formal potential for reduction to proceed at a diffusion-controlled rate. At a transition time, $\tau$, the current is measured and the potential stepped back to its original value. The current is measured again at 2$\tau$. The is essentially a generator–collector experiment and, as shown in Equation (11), the ratio of the currents obtained at $\tau$ and 2$\tau$ are normalized relative to the values that would be obtained in the absence of a following chemical reaction

$$R = \frac{I(2\tau)/I(\tau)}{[I(2\tau)/I(\tau)]_{\text{id}}}$$  \hspace{1cm} (11)$$

Figure 9 shows how $R$ depends on the characteristic time of the experiment, $\tau$, and the concentration of 1-methyl-4-tert-butylpyridinium cation. By combining cyclic voltammetric and potential-step techniques, Savéant has studied more complicated chemical systems such as the methylacridan (AH)/10-methylacridinium ($\text{A}^+$) couple in acetonitrile, which is an analogue of the coenzyme NADH/NAD$^+$ couple. The formal potentials and the heterogeneous electron transfer rates, as well as the reaction rates of the following chemical reactions, were determined. These investigations revealed that oxidation of AH, as well as reduction of $\text{A}^+$, were kinetically controlled by following homogeneous chemical steps, rather than by the initial electron transfer, which appears to be quite fast in both cases.

2.7 Steady-state Electrochemistry

In the preceding sections, we have focused on the use of transient methods to address short timescales in electrochemistry. However, in an electrochemical measurement involving a solution-phase reactant, the appropriate timescale is not necessarily the actual duration of the experiment. Typically, the timescale is imposed by the time taken for diffusion, $t_{\text{id}}$, of the analyte of interest from the bulk solution to the electrode surface or vice versa. In seeking to measure electrochemical kinetics, one seeks to match this diffusion time to the half-life of the chemical process (homogeneous reaction dynamics) or of the interfacial electron transfer process (heterogeneous electron transfer dynamics). In transient methods, $t_{\text{id}}$ is directly related to the duration of the experiment. However, under steady-state conditions, $t_{\text{id}}$ is not related to the actual duration of the experiment since the diffusion-layer thickness depends only on the radius. Under these conditions, $t_{\text{id}}$ is approximately equal to $r^2/D$. This property has a profound impact on the size of microelectrodes required to make measurements at steady state, e.g. given a typical diffusion coefficient of $10^{-8} \text{cm}^2 \text{s}^{-1}$, microelectrodes with radii of less than 30 nm are required to address submicrosecond timescales. Thus, it is clear that probing ultrafast electrochemical processes demands the fabrication of vanishingly small electrodes. However, although specialized, this is not an impossible task and well-characterized band electrodes with widths of 2 nm have been fabricated by sealing a deposited metal film between insulators.

In contrast to transient techniques, a steady-state response is unaffected by charging currents, is insensitive to low levels of reactant adsorption, and requires less complex instrumentation. The choice between transient or steady-state approaches centers on the need to produce a relatively larger, but ideally responding, electrode for transient measurements, e.g. a 25-$\mu$m radius microelectrode will exhibit a submicrosecond RC time constant in high concentrations of supporting electrolyte, compared to the need to fabricate nanometer or even angstrom dimension electrodes for use in a steady-state approach. However, the ability of transient reversal techniques, such as double step chronoamperometry or cyclic voltammetry, to create and subsequently to detect electrochemical intermediates, represents a significant advantage when attempting to characterize reactive intermediates or elucidate reaction mechanisms.
Perhaps the most convenient way to measure the steady-state current is to apply a potential sweep to the microelectrode. The appropriate timescale can be determined as outlined in section 2.4 and this time can then be converted into a scan rate by noting that the characteristic time of cyclic voltammetry is $RT/FV$. It is important to stress that the magnitude of the steady-state current is intrinsic to the size of the microelectrode. It is independent of the technique (e.g. slow-scan voltammetry or long-timescale potential step) and of the direction of the potential scan or step. Moreover, at steady state all concentrations in the vicinity of the electrode surface are unchanging over time.

Figure 10 shows that while reversible, quasi-reversible, and irreversible systems all exhibit sigmoidal-shaped current responses and the same limiting currents in slow-scan voltammetric experiments, the experimental formal potential shifts from its thermodynamic value. This shift arises from competition between kinetic and diffusion control, with less steep curves being obtained for quasi-reversible and irreversible systems. Quasi-reversibility is observed if the kinetic distance of the reaction, $D/k^o$, where $k^o$ is the standard heterogeneous electron transfer rate constant, sufficiently exceeds the dimension of the microdisc (e.g. $D/k^o = 10^4 \text{cm s}^{-1}$). Under these conditions, the difference between the operational and thermodynamic formal potentials can be used to determine $k^o$ without any interference from the charging current. Reversible responses are observed when $D/k^o$ is much smaller than the radius of the microdisc.

This analysis places upper limits on the magnitude of $k^o$ that can be determined using a particular radius microdisc under steady-state conditions. For example, for a 1-µm radius microdisc, the upper limit on the measurable $k^o$ is approximately $10^{-3} \text{cm s}^{-1}$. Using microdiscs of 50 nm, which are about the smallest microdiscs currently routinely available, the upper limit can be extended to about $2 \times 10^{-4} \text{cm s}^{-1}$. However, in practice this upper limit cannot be extended indefinitely by shrinking the electrode. Imperfect seals, often caused by mismatching of the thermal expansion coefficients of the glass shroud and the metallic microwire, often enhance non-Faradaic currents.

Another important consideration when trying to fabricate increasingly smaller microelectrodes is the formation of a microcavity around the electrode tip. Creating a slightly recessed electrode (e.g. because a gold microwire is used that is much softer than the insulating glass shroud), may not significantly compromise the response observed for a 10-µm radius microdisc. However, such a cavity can become very important if the electrode size is reduced to nanometer dimensions, causing distortions that are attributed to kinetic effects to become significant. Moreover, the use of an ion-exchange material as an insulator may lead to a double layer being set up on the shroud, generating an electrical potential that would compromise the measurement of the interfacial kinetics. However, these effects are likely to be important only when the Debye length of the electrolyte (typically 10–100 Å) is larger than the electrode radius. A more important effect arises from surface contamination by impurities found within the analyte, solvent, or supporting electrolyte. It is important therefore to maintain high levels of cell cleanliness and to confirm the pristine state of the electrode surface by measuring the kinetics of a reference system before and after a new analyte is investigated.

2.7.1 Heterogeneous Electron Transfer Dynamics

Understanding the elementary steps involved in heterogeneous electron transfer across a metal/solution interface is of considerable technological importance in areas ranging from battery performance to corrosion inhibition. In trying to use steady-state methods to determine kinetic parameters for fast reactions, experimental conditions are usually chosen so that there is mixed control by kinetics and diffusion. Aoki et al., Fleischmann et al., and Oldham and Zoski have addressed this difficult issue and provided several equivalent approaches for analyzing the experimental current–voltage curves. More recently, Mirkin and Bard developed a new approach to determining kinetic parameters for a simple quasi-reversible electron transfer reaction. In principle, only the one-quarter ($E_{1/4}$), one-half ($E_{1/2}$), and three-quarters ($E_{3/4}$) potentials from a single steady-state voltammogram are required, although more precise values of $k^o$ and $a$, the...
the archetypal reversible couple ferrocene, reported surface impedes diffusion and prevents the current by an insoluble layer. This blocking of the electrode concentrations the electrode becomes pacified used to analyze the data. Moreover, for high ferrocene, solvent and electrolyte, and the method the electrode preparation regime, the purity of the numerous reasons for these discrepancies, including the electrode/solution interface is significantly these data show that the rate of electron transfer coefficient, can be obtained by fitting the full voltammogram. Moreover, the analysis is independent of the electrode area and the concentration of the electroactive species that improves the reliability of the analysis.

The parameters describing the kinetics of heterogeneous electron transfer for several solution-phase redox-active molecules have been reported and a representative sample is given in Table 3. As expected, these data show that the rate of electron transfer across the electrode/solution interface is significantly influenced by the identity of the redox couple. These variations reflect differences in the reaction adiabaticity and activation barriers that exist for the individual systems. However, even for a single species, a considerable range of \( k^o \) values are observed, e.g. for the archetypal reversible couple ferrocene, reported \( k^o \) values range from 0.09 to 220 cm s\(^{-1}\). There are numerous reasons for these discrepancies, including the electrode preparation regime, the purity of the ferrocene, solvent and electrolyte, and the method used to analyze the data. Moreover, for high ferrocene concentrations the electrode becomes pacified by an insoluble layer. This blocking of the electrode surface impedes diffusion and prevents the current observed from increasing proportionally with increasing ferrocene concentration. Thus, even for the standard electrochemical test system considerable care must be taken over all aspects of the experiment, chemicals, electrode preparation, experimental setup, as well as data collection and analysis if accurate kinetic parameters are to be obtained.

2.7.2 Homogeneous Chemical Kinetics

A second important application of steady-state measurements is in studies of chemical reactivity. Steady-state measurements using electrodes of different radii can provide a powerful insight into the kinetics of homogeneous reactions where the limiting current density depends on the magnitude of the homogeneous rate constant. Hence, as described in Table 4, coupled chemical (C) and electron transfer (E) reactions (e.g. EC mechanisms), catalytic follow-up processes, as well as reactions involving DISP have been characterized. It is important to note that reactions, such as chemical reactions that follow electron transfer mechanisms, cannot be investigated in the same way since the current density is not influenced by the following chemical reaction. In these circumstances, the

\(^a\) Dimension given is the radius of a microdisc electrode unless otherwise stated.

homogeneous reaction does not affect the height or shape of the reversible steady-state voltammogram. However, as indicated by Figure 11, the position of the wave on the potential axis depends on the homogeneous reaction rate, and kinetic information can be obtained by probing how \(E_{1/2}\) depends on the electrode radius.

The technique is best applied to reactions whose rate constants are of the same magnitude as \(D/r^2\). Therefore, given that it is now feasible to fabricate microelectrodes with submicrometer critical dimensions, the dynamics of first-order chemical reactions with rate constants between \(10^2\) and \(10^4\) s\(^{-1}\) can be investigated.

3 INDIRECT METHODS

As discussed above, with direct electrochemical measurements a competition is created between the reaction of interest and diffusional mass transport either by controlling the time over which the system is electrochemically perturbed (transient methods) or by controlling the electrode size (steady-state methods). In both approaches, diffusion provides a time reference for the measurement. In contrast, for indirect methods, the reaction of interest competes with another chemical reaction whose rate constant is known from independent measurements. Thus, this second reaction acts as a kinetic reference instead of the diffusion to or from the electrode that applies in the direct methods.

Competitive preparative-scale electrolysis is an approach that can provide a limited insight into the relative rates of reactions. Here, the distribution of products between two competitive reactions is measured, one of which is the reaction of interest and the other is known from the independent sources and acts as reference. For example, Savéant et al.\(^{81}\) have investigated the competition that takes place between electron and...
hydrogen atom transfer pathways for the reduction of aryl halides in H-atom donor solvents such as acetonitrile and dimethylsulfoxide (DMSO). Mathematical models describing how the product distributions depend on the reaction mechanism and rate constant have been determined. Not only do these analyses provide important fundamental information about those factors that control chemical reactivity, they also allow important industrial processes to be optimized, e.g. reduction of CO₂ in media of low proton mobility.

### 3.1 Redox Catalysis

Redox catalysis can be viewed as the ultimate limit of small probe electrochemistry in which the electrode is decreased to the size of a single molecule. Figure 12 illustrates how the dynamics of an electron transfer reaction can be probed using a mediator in a redox catalysis scheme. Only the case in which the dynamics of a reduction reaction are being probed is considered.

In this approach, a substrate A that would normally be reduced at an electrode surface is now reduced by a mediator Q, i.e. the mediator Q replaces the electrode surface and reduces the substrate A. If the reduced form of the redox couple of interest undergoes a following chemical reaction, then its decay can be monitored using this approach. Figure 13 illustrates the differences between redox catalysis and direct electrochemistry.

While it provides great insight into a wide variety of reaction mechanisms, the useful time domain of this technique is somewhat unusual in light of the discussion on direct methods. Redox catalysis is only useful for monitoring species with lifetimes less than approximately 10μs. As discussed previously, the rate of diffusion increases with decreasing electrode size. In redox catalysis, the electrode has been reduced to the dimensions of a single molecule allowing extremely low timescales to be accessed. In the case where the driving force is large (i.e. large values of \( E_{\text{PQ}} - E_{\text{AB}} \)), \( k_r \) will have a value close to the diffusion limit. Taking a maximum value of 50 mM for \([P]_0\), it is apparent that the shortest measurable lifetime, \( k [P]_0 \), is of the order of 50 ns.

In redox catalysis, the current flowing through the electrode is monitored. The mediating P/Q couple is selected to be electrochemically fast and reversible as well as having a standard potential located positive of the substrate (A) reduction wave. Thus, in cyclic voltammetry experiments performed on the mediator alone, reversible on-electron waves are observed even at high scan rates because the rate of heterogeneous electron transfer is fast. However, when the analyte of interest is added, the voltammetry for the mediator becomes irreversible and the reduction current increases. These effects provide kinetic information about the electron transfer and coupled chemical reactions. As illustrated in Figure 13, the rate-determining step is either the forward electron transfer or the homogeneous chemical reaction with the electron transfer step acting as a pre-equilibrium. It is the competition that exists between the backward electron transfer step and the chemical reaction that dictates which process will be rate determining.

The work of Utley et al. on ortho-quinodimethanes (o-QDM) provides a good illustration of how redox catalysis affects the voltammetric response. As illustrated in Figure 14, co-electrolysis of 1,2-bis(bromomethylarenes) and dienophiles (e.g. maleic anhydrides or quinones), gives the Diels-Alder adduct expected for reaction of the o-QDM derived from the dihalide. It is known that direct reduction of the dihalides gives o-QDMs but in the absence of a dienophile they polymerize. However, Utley performed co-electrolysis experiments at a potential several hundred millivolts more positive than the reduction potential of the dihalide. Cyclic
voltammetry of this system is illustrated in Figure 15 which shows that a chemically reversible reduction is observed for the mediator (dienophile) in the absence of the dihalide. Moreover, this reversible response is observed at slow scan rates, indicating that the radical-anion is stable over a significant lifetime. However, in the presence of the analyte of interest, the radical-anion can transfer an electron to the added dihalide, which rapidly undergoes a following chemical reaction, i.e. it loses bromide anion. As shown in Figure 14, at long times an o-QDM is formed, which can react relatively slowly with the regenerated mediator. On the cyclic voltammetry timescale the regenerated mediator is rapidly reduced, with the regenerated mediator. On the cyclic voltammetry an

\[
\frac{d[P]}{dr} = -\frac{d[Q]}{dr} = -\frac{d[A]}{dr} = k_{+}[A][Q] / k_{-}[P] + k
\]

Kinetic control by the forward electron transfer step, Equation (13)

\[
\frac{d[P]}{dr} = -\frac{d[Q]}{dr} = -\frac{d[A]}{dr} = k_{+}[A][Q]
\]

is achieved when \(k_{-}[P]_0 \ll k\). In contrast, when \(k_{-}[P]_0 \gg k\), the kinetics of the homogeneous chemical reaction are rate determining, Equation (14)

\[
\frac{d[P]}{dr} = -\frac{d[Q]}{dr} = -\frac{d[A]}{dr} = k_{+} k_{A}[A][Q] / k_{-}[P]
\]

This analysis reveals that the rate-determining step depends on the concentration of the mediator, \(P\), and can be switched from electron transfer to homogeneous chemical reaction by changing \([P]_0\). Solutions to these systems of differential equations have been obtained for a wide variety of electrochemical techniques, including cyclic voltammetry and chronoamperometry, allowing rate data to be obtained for unstable intermediates having lifetimes down to the low nanosecond time range.

The technique has certain limitations, e.g. if the chemical reaction is so fast that the kinetic control is always by the forward electron transfer step then it is not possible to characterize the homogeneous chemical reaction kinetically. However, under these conditions it is often still possible to measure the formal potential and heterogeneous electron transfer rate constant for the A/B couple if experiments are conducted using a range of mediators with different formal potentials. Savéant et al. \(^8\) have elucidated the relationship between the electron transfer rate constant and the formal potential of the PQ couple where the homogeneous chemical reaction is so fast that it occurs within the molecular diffusion layer of the mediator. Moreover, this group has extended the theory to allow more complex reaction schemes, including bimolecular following reactions, than the electron transfer reaction described above to be characterized. These advances are significant since simple electron transfer reaction schemes are rarely found in real experimental systems.

### 3.2 Indirect Laser-induced Temperature Jump Method

There is a long and distinguished record of using temperature jump to elucidate the kinetics of homogeneous chemical phenomena, e.g. Sutin et al. \(^8\) used a laser-induced temperature jump method to achieve rise times of tens of nanoseconds. Moreover, approaches have been developed to allow the temperature of the electrode/solution interface to be rapidly changed. However, electrical heating methods typically allow the interfacial temperature to be perturbed only at the millisecond or longer timescale. The use of lasers has radically changed this field allowing much more rapid temperature jumps to be achieved allowing fast electron transfer processes to be investigated. These laser-based approaches stem from early work in which laser flashes impinged on the electrode/solution interface causing electrons to be photoemitted. For example, Barker et al. \(^8\) studied the effects of irradiation by a 20 ns laser pulse (\(\lambda = 694.3\) nm) on mercury and suggested that laser-induced temperature changes might be the cause of some of the observed potential changes since the laser energy was insufficient to cause photoemission at the applied potentials investigated. This “front side” irradiation approach without stimulated photoemission was also used by Benderskii
et al.\(^{85}\) to examine double-layer phenomena at mercury electrodes with nanosecond time resolution. Coufal and Hefferle\(^{86}\) have also demonstrated the ability of laser-induced temperature steps to resolve nonelectrochemical events at subnanosecond timescales.

An extremely important variation on these approaches has been developed by Feldberg and co-workers.\(^{87}\) Their indirect, the indirect laser-induced temperature jump method (ILIT) involves indirect irradiation of the electrode, i.e. the laser pulse impinges on the “back face” or nonelectrolyte electrode surface. In this method, some of the incident photons are absorbed by the thin foil or film electrode and thermalise virtually instantaneously causing a rapid rise in the interfacial temperature. The time dependence of the thermal perturbation is determined by the shape of the laser pulse and by the thickness, thermal diffusion constant, and heat capacity of the electrode material, also the heat capacities and thermal diffusion constants of the two adjacent media (electrolyte at the front face, and dielectric surrounding the rear of the electrode). Typically, this interfacial temperature jump destroys the equilibrium between the double-layer potential and the redox potential. This process changes the open-circuit potential as the system attempts to re-establish equilibrium under the new conditions. In contrast to classical charge-injection methods, thermal perturbation does not cause a large \(iR\) spike, making data interpretation more straightforward. Moreover, the ILIT offers the possibility of extracting information about thermal as well as electrochemical properties of electrodes and adsorbed layers.

When compared with direct irradiation of the electrode/solution interface, Feldberg’s indirect approach has several advantages. Photoemission of electrons into the solution is not possible; the optical density of the solution is irrelevant and photolysis and/or direct thermal heating of the solution is avoided; the form of the interfacial temperature perturbation approximates a step function more closely than that associated with direct irradiation; deconvolution of the data is facilitated and the rates of the rise and fall of the interfacial temperature can be adjusted (but not independently) by changing the thickness of the electrode.

There are three major processes that can cause the open-circuit potential to change in response to the temperature jump. First, there is a junction potential between the (hot) electrode and the (cold) contact wire. Second, a change occurs in the potential across the electrode double layer which can be caused by a change in the capacitance or dipole reorientation (equivalent to a change in the potential of zero charge); by charge transfer (electron transfer between the electrode and a redox system) located at the outer Helmholtz plane (solution-phase reactant) or inner Helmholtz plane (adsorbed reactant), or ion transfer between the inner and outer Helmholtz planes. Third, a Soret potential arises from the temperature gradient between the interfacial region and the bulk electrolyte. Therefore, this approach can be used to determine kinetic and thermodynamic parameters of potential-dependent double-layer restructuring, heterogeneous electron transfer to the solution phase and adsorbed electroactive species and ion transfer from the inner to outer Helmholtz planes, all at nanosecond or shorter timescales. The theoretical analysis for each of these situations yields an analytic equation provided that the temperature changes are small (controllable through the laser power) and the charge-transfer resistance is constant.

As an example, determination of the heterogeneous electron transfer rate constant for ferro/ferri cyanide and the ways in which ILIT can provide a powerful insight into adsorption phenomena are reviewed here. As illustrated in Figure 16, the typical ILIT experiment uses a Nd:YAG laser (\(\lambda = 1.06\mu m\), full width at half height maximum of 8 ns) that is capable of resolving relaxations as short as 10 ns. The pulse from this laser passes through a neutral density filter that allows the incident power to be controlled before being directed by a mirror onto the back surface of the working electrode. As shown in Figure 17, the cell contains two cylinders of 25\(\mu m\) Pt foil approximately 1 cm wide. One cylinder acts as a pseudoreference electrode against which the change in the open-circuit potential is measured while the other is used as an auxiliary electrode for a three-electrode potentiostat.

Figure 18, illustrates examples of the ILIT responses obtained for a 1.07\(\mu m\) gold film electrode in contact with 1.0 M KF before and after the addition of 4\(\times 10^{-2}\) M of \(K_2[Fe(CN)]_6\) and \(K_4[Fe(CN)]_6\). In both cases the electrode potential is poised at the formal potential of the redox couple. The magnitude of the ILIT response is of the order of a few millivolts and is typical of these experiments. In the absence of
any dissolved electroactive species, the open-circuit potential changes abruptly within a few nanoseconds and then relaxes over several hundred nanoseconds. Both before and after addition of the electroactive species, simple thermal responses are obtained, i.e. the change in the open-circuit potential precisely follows the change in the interfacial temperature. Moreover, the time dependence of these responses follow, almost exactly, that predicted by theory. Analyzing the ILIT response in the presence of the electroactive species provides a value of \(1.64 \times 10^{-2} \text{cm s}^{-1}\) for the standard heterogeneous electron transfer rate constant which is in reasonable agreement with previous results obtained using traditional electrochemical techniques.

Implicit in the analysis is the assumption that the change in the interfacial temperature does not cause the rate constant to change significantly. For the case of the Fe(CN)\(_{6}^{3-/-}\) couple, the activation energy is of the order of 13 kJ mol\(^{-1}\) so that changes in the electrode temperature of up to 4 K will result in \(k^0\) being constant to within 10\%. However, for reactions featuring large activation energies, e.g. those with large inner or outer sphere reorganization energies, temperature-induced changes in \(k^0\) may be significant.

Although the open-circuit potential becomes constant with time in all cases, suggesting that equilibrium is achieved, the magnitude of the ILIT response depends on the concentration of the ferrocyanide and ferricyanide. While effects such as adsorption of an impurity, electron transfer between the electrode, and solution-phase reactant cannot be excluded, this observation is considered to arise because of Fe(CN)\(_{6}^{3-/-}\) adsorption onto the electrode surface. Adsorption will modify the structure of the electrochemical double layer thus changing the thermal response. The concentration-dependent \(\Delta V_t\) can be used as a measure of the surface coverage of the adsorbate and the concentration-dependent surface coverage modeled using the Frumkin adsorption isotherm. This analysis reveals that the Fe(CN)\(_{6}^{3-/-}\) layer is strongly bound, \(K_{ads} = 4.7 \times 10^9 \text{M}^{-1}\). That positive values of the interaction parameter, \(g\), are observed suggests either that there are strong repulsive interactions between the adsorbates, or that the potential difference between the inner and outer Helmholtz planes changes with changing surface coverage.

A very important example of the ultrafast capabilities of this method is in the determination of heterogeneous electron transfer rate constants for electroactive self-assembled monolayers. As discussed in the section dealing with fast transient methods, when a short bridge is used to tether the redox active species to the electrode surface, the rate of heterogeneous electron transfer becomes immeasurably fast even for chronocoulometry at microelectrodes. The ILIT was used to probe the kinetics of electron transfer between a gold electrode and a self-assembled monolayer formed from CH\(_3\)(CH\(_2\))\(_n\)-SH and

![Diagram of the ILIT cell](image-url)
(n^5−C_5H_5)Fe(n^5−C_3H_4)CO_2(CH_2)_nSH (i.e. a diluted ferrocene alkane thiol monolayer), where n is the number of methylene groups in the bridge and 5 \leq n \leq 9. In these experiments, as well as recording the time-dependent change in the open-circuit potential, the size of the temperature jump at the electrode/electrolyte interface was monitored using a pressure transducer.

Figure 19 shows the ILIT response obtained close to the formal potential of the ferrocene/ferricenium redox reaction for a gold film electrode modified with a ferrocene alkane thiol monolayer in which the bridge contains five methylene groups. Fitting these data using theory developed for heterogeneous electron transfer involving a surface confined species provides an estimate of k as 7.8 × 10^7 s^{-1}. This value is comparable with the upper limit of that possible using state-of-the-art transient chronoamperometry. By controlling the applied potential, the potential dependence of the heterogeneous electron transfer rate constant can be determined. For this system, this dependence appears to be adequately described by the Butler–Volmer formalism of electrode kinetics.

![Figure 19](image)

**Figure 19** ILIT response obtained for a gold electrode coated with a mixed monolayer formed from CH_3(CH_2)_4SH and (n^5−C_5H_5)Fe(n^5−C_3H_4)CO_2(CH_2)_nSH with N_f = 1.3 \times 10^{-10} mol, T = 31.0 °C, thickness of the electrode = 0.96 \times 10^{-3} cm. Open circles are the experimental data. E_{app} = 0.475 V vs standard SCE, solid line is the theoretical fit. The dotted line represents the response which would be observed if there were no relaxation of the ILIT signal caused by electron transfer between the electrode and the redox couple. (Reprinted with permission from J.F. Smalley, S.W. Feldberg, C.E.D. Chidsey, M.R. Linford, M.D. Newton, Y.-P. Liu, J. Phys. Chem., 99, 13 141. Copyright (1995) American Chemical Society.)

Beyond potential-dependent rate constants, the approach was extended to measure activation (reorganization) energies by using a thermostated cell. Figure 20 shows that the electron transfer rate constant depends on the number of methylene groups in the bridge. At 25 °C, the standard electron transfer rate constants vary according to k_{0,s,n=0} \exp(-b_n \Delta f) where k_{0,s,n=0} is the extrapolated rate constant for the electron transfer at n = 0 and is equal to 6 × 10^8 s^{-1} and b_n is 1.21 ± 0.05. Moreover, for each of the monolayers investigated, linear Arrhenius plots are observed. The slopes of these plots have been used to determine the reorganization energy, λ, assuming that λ is the sole contributor to the activation energy for electron transfer. The reorganization energies range from 0.70 ± 0.04 eV for n = 5 to 0.91 ± 0.05 for n = 9.

3.3 Scanning Electrochemical Microscopy

Bard et al. have developed an important technique, SECM, in which a small electrode is precisely positioned close to a surface in an electrochemical cell arrangement to obtain information about the surface topography and reactions that occur in the solution space between tip and sample. As described in Equation (10), at long timescales a steady-state potential-independent current is observed for the oxidation or reduction of an
Figure 21 Basic principles of SECM. (a) With the microelectrode far from the substrate, diffusion of O leads to a steady-state current, \( i_{T,\infty} \). (b) With the microelectrode near an insulating substrate, hindered diffusion of O leads to \( i_T < i_{T,\infty} \). (c) With the microelectrode near a conducting surface, positive feedback of O to the tip leads to \( i_T > i_{T,\infty} \). (Reproduced with the permission of the Royal Society of Chemistry from M. Arca, A.J. Bard, B.R. Horrocks, T.C. Richards, D.A. Treichel, *Analyst*, 119, 719 (1994).)

Electroactive species at a microelectrode. Figure 21 shows how the current to this microelectrode tip is perturbed by the presence of a substrate near the tip. These effects form the basis of the SECM technique. When the tip is brought near a nonconducting surface, the current will be smaller than the steady-state value of Equation (10) because the surface blocks diffusion of the redox active species to the tip. The closer the tip is to the surface, the smaller the current, until when the tip-to-surface spacing, \( d \), becomes zero, the tip current will approach zero. The tip current, \( i_T \), as a function of separation from the surface can be approximately described by Equation (15)

\[
\frac{i_T}{i_{T,\infty}} = 0.292 + \frac{1.515}{L} + 0.655 \exp \left( \frac{-2.4035}{L} \right)^{-1}
\]

where the normalized tip–substrate separation, \( L \), is equal to \( d/r \). Thus, the presence of a nonreactive substrate near the tip can always be recognized by the condition \( i_T < i_{T,\infty} \).

A different behavior is observed when the tip is near a surface where tip-generated product can be re-oxidized or re-reduced, e.g. when the substrate is a conductive material at a sufficiently positive or negative potential. Under these circumstances, there is a flux of the analyte to the tip from both the substrate and the bulk solution. Owing to this positive feedback from the substrate, \( i_T > i_{T,\infty} \). When the redox reaction occurring at the surface proceeds at a diffusion-controlled rate, Equation (16) applies

\[
\frac{i_T}{i_{T,\infty}} = 0.68 + \frac{0.738}{L} + 0.3315 \exp \left( \frac{-1.0672}{L} \right)
\]

Figure 22 shows approach curves, i.e. plots of \( i_T/i_{T,\infty} \) versus \( L \) for the cases where the microelectrode tip approaches conducting and nonconducting surfaces.

An important attribute of the technique is that if the electrode radius is known, the Faradaic current can be used to determine the tip–surface separation without having prior knowledge of the bulk concentration or diffusion coefficients.

Figure 22 Diffusion controlled steady-state tip current as a function of tip–substrate separation. \( i_T = i_T/\iota_{T,\infty} \). \( L = d/r \). (a) Substrate is a conductor, (b) conductor is an insulator. The solid lines are theoretical fits. (Reproduced with the permission of the Royal Society of Chemistry from M. Arca, A.J. Bard, B.R. Horrocks, T.C. Richards, D.A. Treichel, *Analyst*, 119, 719 (1994).)
3.3.1 Heterogeneous Electron Transfer Dynamics

SECM has recently emerged as a useful technique for measuring the rate constants of fast heterogeneous electron transfer reactions. To achieve this objective, the SECM apparatus is used to form a twin-electrode thin-layer cell between the microelectrode tip and a conducting substrate. During voltammetric scans, this configuration induces high rates of mass transfer between the substrate and tip electrodes because large concentration gradients exist between the two closely spaced electrodes. The overall current observed can be limited by either the rate of mass transfer to the electrode or the intrinsic heterogeneous electron transfer rate. Therefore, the increase in mass transfer of the thin layer cell allows faster rates of electron transfer to be measured in the SECM arrangement than can be accomplished with the same electrode in bulk solution.

Most electrochemical responses are sensitive to the heterogeneous electron transfer rate whenever the rate of mass transfer is of the same order of magnitude or greater than the standard heterogeneous electron transfer rate constant. The advantage of SECM can be seen by comparing mass-transfer coefficients for two different electrode configurations. For a microdisc in bulk solution, the steady-state mass-transfer coefficient is approximately \( D/r \). For thin-layer cells, the mass transfer coefficient is approximately \( D/d \). However, while the smallest well-characterized microdisc electrodes are of the order of 500 nm, stable layers as thin as 40 nm have been obtained for a 1-µm diameter Pt disc electrode opposed by a mercury substrate. Clearly, the rate of mass transfer can be enhanced by more than an order of magnitude in going from a microelectrode in bulk solution to the thin-layer configuration in SECM. Achieving a 40 nm substrate to tip separation allows rate constants of the order of several centimeters per second to be measured under steady-state conditions.

Figure 23 shows experimental data and theoretical calculations for the oxidation of ferrocene system taken at different tip–substrate separations. This figure shows that the wave broadens as the tip–substrate separation decreases and the limiting current increases owing to enhanced feedback of the analyte by reaction at the conducting substrate. More significantly, however, the waves broaden because the mass-transfer rate increases to the point where it becomes comparable to, or greater than, the electron transfer rate. It is this increased sensitivity of the voltammetric response to \( k \) that allows large rate constants to be measured under steady-state conditions. The measured \( k^0 \) for ferrocene was \( 3.7 \pm 0.6 \text{ cm s}^{-1} \), confirming the rapid nature of heterogeneous electron transfer in this system.

3.3.2 Homogeneous Chemical Kinetics

SECM can also be used to measure the rate of homogeneous chemical reactions that follow oxidation or reduction by monitoring the effect of the reaction of interest on the tip current. For example, in the case of a reversible redox reaction, when \( d \) is small and the substrate area is large in comparison to the microelectrode tip, essentially all of the material that is electrogenerated at the tip is collected by the substrate. However, a following chemical reaction will consume some of the tip product, decreasing the collection efficiency. In this sense, the tip and substrate electrodes act as a generator–collector assembly in an analogous way to the ring and disc electrodes in a rotating ring-disc electrode. Theory that describes both first- and second-order homogeneous chemical reactions following electron transfer has been developed. This theory is most accessible in the form of working curves describing how the currents observed at both tip and substrate depend on their mutual separation.

A typical reaction scheme which can be studied by SECM is shown by Equation (17)

\[
\begin{align*}
\text{tip:} & \quad \text{R} \rightarrow O + ne^- \\
\text{gap:} & \quad 2O \rightarrow \text{products} \\
\text{substrate:} & \quad O + ne^- \rightarrow \text{R}
\end{align*}
\]
Rate constants can be determined if the tip and substrate are positioned sufficiently close so that a detectable amount of $R$ can cross the gap before reacting. The time required for a species to cross the gap is approximately $d^2/D$. Given that the half-life of the electrogenerated intermediate undergoing a second-order following reaction is $1/kC$, where $C$ is the bulk concentration, rate constants as large as $10^8$ M$^{-1}$ s$^{-1}$ can be measured using separations of the order of 100 nm. For unimolecular reactions, first-order rate constants as large as $10^5$ s$^{-1}$ are measurable.

Bard et al. used the SECM technique to investigate the reductive coupling of dimethyl fumarate as well as fumaronitrile in DMF. For fumaronitrile, the rate constant was shown to be approximately constant as the analyte concentration was changed over two orders of magnitude. This consistency indicates that second-order kinetics are being followed for the following chemical reaction of the fumaronitrile anion radical. The measured rate constant is large, $2 \times 10^3$ M$^{-1}$ s$^{-1}$, demonstrating the ability of SECM to provide high-quality kinetic information about fast homogeneous chemical reactions. In contrast, the other alkene, dimethyl fumarate, appears to be less activated and undergoes a much slower chemical reaction when reduced and a rate constant of 170 M$^{-1}$ s$^{-1}$ was determined using both tip feedback and substrate current measurements. Good agreement of experiment with theory was seen for both modes of SECM operation.

Despite the rapid nature of these processes, Bard and his group have extended the use of SECM to the study of even faster reactions, e.g., the dimerization of 4-nitrophenolate, which has been shown to undergo a fast irreversible dimerization following oxidation. The calculated rate constant, approximately $8 \times 10^7$ M$^{-1}$ s$^{-1}$, agrees well with that measured by fast-scan cyclic voltammetry.

4 FUTURE DIRECTIONS

4.1 Analytical Applications of Fast Electrochemistry

When attempting to determine the concentration of a particular redox active species in a complex mixture, the response of the target analyte is typically separated from redox active interferences on the basis of different formal potentials. In fact, there have been relatively few reports using differences in electrochemical reactivity (i.e., electrode kinetics) to determine the concentration of a target analyte by separating its voltammetric response from that of an interferent on the basis of different time constants for the two reactions. Since the width of the electrochemical response for any species is a sizable fraction of the potential scale, relying on the potential axis alone to generate a selective response provides only a very limited ability to resolve an analyte’s response from that of an interfering species. If the time axis as well as the potential axis can be used, separating the analyte’s response from that of an interfering species becomes considerably more likely. This time-resolved approach ought to benefit significantly from the dramatic expansion in the range of timescales that can be resolved and exploited in electrochemistry with the advent of high-speed instrumentation and microelectrodes.

It is widely recognized that double-layer charging can represent a significant obstacle to achieving very low limits of detection in electroanalysis. Often, background subtraction is achieved by measuring the voltammetric response in the absence of the electroactive species of interest. However, differences in rates at which charging and Faradaic processes occur can be exploited to time gate the response so that an enhanced Faradaic to capacitive current ratio is obtained.

4.2 Ultimate Limits on Ultrafast Electrochemical Techniques

Decreasing the timescale of $t_{diff}$ of an electrochemical experiment involving a solution-phase reactant can be achieved either by shortening the experimental timescale (faster voltammetric scan rates or shorter potential steps), or by shrinking the critical dimension of the microelectrode in steady-state measurements. Both of these effects cause the thickness of the diffusion layer to shrink and it will eventually become less than that of the electrochemical double layer. This effect has profound consequences for migration of the analyte within the electric field of the double layer.

In conventional electrochemical cells containing a dilute ($\leq 0.1$ M) supporting electrolyte, the electrical field that exists because of the electrode–solution potential difference decays exponentially from the electrode surface out into solution over a distance of a few tens of angstroms. Under these conditions, the effects of diffusion or migration within the double layer are negligible. In classical electrochemical theories, it is assumed that the concentrations of charged species within the interfacial region are described by a Boltzmann distribution imposed by the electrical potential of the double layer. Further out in solution, diffusion is the mechanism of mass transport of molecules and ions. The Frumkin correction allows the true electrode concentrations to be related to those existing at the end of the electrochemical double layer. While these concentrations do not represent those actually found at the electrode surface, they are usually used as boundary conditions in solving diffusion problems.
The difficulty with the Frumkin approximation arises when dealing with ultrafast electrochemical techniques since the sizes of the double and diffusion layers become comparable. Therefore, using the concentrations found at the end of the interfacial region as a boundary condition ceases to be appropriate. For example, given a typical diffusion coefficient of $10^{-5}$ cm$^2$ s$^{-1}$, the diffusion layer thickness will be of the order of 100 Å for a cyclic voltammetry experiment in which the scan rate is 300 000 V s$^{-1}$ or for a 10 nm electrode in a steady-state measurement. This diffusion-layer thickness is comparable to the typical double-layer thickness. The difficulty arises because the voltammetric response will no longer be controlled by diffusion alone but migration within the double layer will influence the observed response.

Recently, two models describing this mixed control situation have been developed for transient and steady-state methods. Both of these models predict that the voltammetric waves appear to be kinetically controlled by heterogeneous electron transfer when analyte migration within the double layer becomes important. However, the predicted behavior contrasts with that predicted by conventional theories of electrode kinetics. In the Butler–Volmer formalism of electrode kinetics, the heterogeneous electron transfer rate constant is expected to increase without limit as the overpotential (electrochemical driving force) is increased. However, coupling between diffusion and migration in the interfacial region causes the apparent heterogeneous electron transfer rate constant eventually to become potential independent, corresponding to the maximum rate, not of electron transfer, but of the reactant crossing the double layer. Further decreases in the critical dimension of ultramicroelectrodes used in steady-state measurements, and the timescale of transient electrochemical techniques, will allow further testing of these theories to be performed.

In order to achieve faster perturbation of the chemical system in transient measurements, it will be necessary to generate pulse signals with rise and fall times on the picosecond timescale if deconvolution of the instrumental and electrode responses is to be avoided. With the development of ever faster chips (e.g. even personal computers have cycle times on the order of nanoseconds), programmable pulse generators with this performance level are becoming more widely available commercially. Another key issue is the transduction of the fast current response. The transient current response for electrodes with subnanosecond RC time constants will be on the nano- and even picoamp scale. One strategy for detecting these very small currents with high speed is to insert a second stage of amplification following fast current-to-voltage conversion. Amplifiers of this type that operate at gigahertz frequencies are also available, although their cost is high. Ultrahigh-speed transient digitizers with gigahertz bandwidth and gigahertz sampling rate are also available. However, the total cost of assembling such a system with low to subnanosecond time resolution would be of the order of $175 000.

5 CONCLUSIONS

This article has attempted to convey the significant new insights and opportunities that ultrafast electrochemical techniques have provided. This revolution in electrochemistry has greatly extended the range of conditions of solvent, temperature, and timescale under which it is now possible to obtain information about redox processes directly. In particular, today microelectrodes allow experiments (e.g. voltammetry in oil or concrete) to be performed that would simply have been impossible a few years ago. This advance has not only revolutionized the field internally, it has broadened the impact of electrochemistry into new dimensions of space and time, e.g. microsecond monitoring of neurotransmitter release with single-cell spatial resolution.

REFERENCES

This article reviews the field of solution-phase ultraviolet/visible (UV/VIS) absorption spectroelectrochemistry and its application to problems in thermodynamics, kinetics, and mass transport, with emphasis on both experimental and theoretical aspects. Examples are provided for transmission in thin layer and semi-infinite media, using optically transparent electrodes, and external and internal reflection in quiescent media. Also illustrated is the coupling of UV/VIS spectroscopy to systems under forced convection, such as rotating disk and channel electrodes, under steady state and transient conditions. Attention is also focused on spatially resolved spectroelectrochemistry for the imaging of diffusion and reaction layers. The last section is devoted to the more complex and particularly powerful modulation techniques involving diffraction, refraction and absorption in stagnant media and in the presence of convective flow. Factors that limit the sensitivity and spatial and temporal resolution of UV/VIS absorption spectroelectrochemistry, as well as its future prospects in analytical chemistry are briefly discussed.

1 Introduction

Light in the UV/VIS range, i.e. 190–700 nm, can promote excitation of electronic states in atomic and molecular species in gas and solution phases, and also in condensed matter, including crystalline solids and pure liquids. As such, it represents a valuable probe of the structure and properties of materials.\(^{(1-3)}\) UV/VIS spectroelectrochemistry refers collectively to a wide array of techniques that employ radiation in this frequency domain for the study of the optical properties of electrodes and electrolyte solutions, particularly those induced by changes in the applied potential across electrode–solution interfaces.\(^{(4-8)}\) Implicit in this definition is the fact that measurements are performed in situ, i.e. with the electrode immersed in the solution under potential control. Particularly amenable to UV/VIS spectroelectrochemical investigation are electrode processes that generate soluble species that absorb radiation in this spectral region, elicit spatial variations in the index of refraction, or modify the optical properties of interfaces. The dependence of the molar absorptivity on the wavelength of the probing beam, which is often specific to each and every chromophore, provides an added dimension for the identification and monitoring of species involved in electrochemical reactions as compared to simple current–potential relationships.

This article reviews the field of solution phase UV/VIS absorption spectroelectrochemistry and its application to problems in kinetics, mechanisms and mass transport. Within this rather narrow scope, it excludes equally important areas that rely on the analysis of light reflected from the electrode surface, such as ellipsometry\(^{(9,10)}\) and electroreflectance,\(^{(11,12)}\) as well as simple refraction, notably probe beam deflection\(^{(13)}\) and interferometry,\(^{(14)}\) for the study of interfacial and bulk phenomena. As the vast majority of heterogeneous electron transfer reactions involve generation or depletion of species in solution, diffusion plays an important role in controlling the current that flows across the interface and, thus, the time evolution of concentration profiles.\(^{(15)}\) Hence, it is of key importance to highlight at the outset fundamental aspects of the two most relevant physical phenomena, namely, the interaction of light and matter, and mass transport of species in condensed media, to gain a full appreciation of the various factors associated with the design and interpretation of spectroelectrochemical experiments.
2 THEORETICAL CONSIDERATIONS

2.1 Optics

2.1.1 Light Propagation through Single-phase Materials

The optical properties of an isotropic nonmagnetic media are defined in terms of its complex refractive index \( n = n - ik \), or its complex dielectric function, \( \varepsilon = \varepsilon' - i\varepsilon'' \), where the index of refraction \( n \) and the extinction coefficient \( k \) are both functions of the wavelength \( \lambda \), and \( \varepsilon' = (n^2 - k^2) \) and \( \varepsilon'' = 2nk \).\(^{16,17} \) Modifications in the composition of an otherwise homogeneous solution, such as those derived from electrode processes, will often bring about variations in the local magnitudes of \( n \) and \( k \), so that the intensity, as well as the direction of light propagating through the media may be altered. These effects can be exploited to obtain time- and space-resolved concentration profiles, allowing important aspects of electrochemical systems to be investigated, including identification of products of redox reactions, measurements of diffusion coefficients, elucidation of reaction mechanisms, and determination of the rates of both heterogeneous and homogeneous electron transfer reactions involving electrogenerated species.

Correlations between \( n \) and \( k \), and the concentration of a single species in solution are usually linear, a factor that simplifies considerably the analysis of experimental data. Furthermore, if ionic migration in an electric field is sufficiently minimized, for example by using an excess of supporting electrolyte, mass transport under either quiescent or laminar flow conditions can be approximated by relatively simple differential equations, allowing solutions to be expressed in terms of common analytic functions. It is precisely the interaction of light with such spatially and temporally varying concentration fields that constitutes the basis for a rigorous mathematical treatment of spectroelectrochemical experiments that rely on absorption, refraction, and diffraction of light. In view of the nature of the material being reviewed, it seems appropriate to focus general attention on light absorption, and defer discussion of refraction and diffraction to those few specialized sections where methods based on these phenomena are introduced.

2.1.2 Absorption

The instantaneous attenuation in the intensity \( I \) of a collimated light beam propagating along an axis \( y \), \(-dI\), through a media of thickness \( dz \), containing, without loss of generality, a single absorbing species, is most often proportional to the intensity of the light incident on the infinitesimal volume, \( dx \, dy \, dz \), to the local concentration \( c(x, y, z, t) \), and to the molar absorptivity of that species \( \varepsilon(\lambda) \):

\[
-dI(x, y, z, t) = I(x, y, z, t)\varepsilon(\lambda)c(x, y, z, t) \, dy
\]

In Equation (1) \( \varepsilon(\lambda) = k\varepsilon(\lambda) \), \( k = 2.303 \), and \( \lambda \) is the wavelength of light at which the measurements are being carried out. The intensity of the light emerging from a cell of length \( d \) along \( y \), \( I(x, d, z, t) \), is given by Equation (2),

\[
I(x, d, z, t) = I(x, 0, z) \exp \left[ -\int_0^d \kappa(\lambda)c(x, y, z, t) \, dy \right]
\]

where, for simplicity, the intensity of the beam incident on the cell, \( I(x, 0, z) \), has been assumed independent of time. Equation (2) can be integrated over the entire cross-sectional area of the beam \( x \, z \), to yield Equation (3)

\[
I(x, d, z, t) = I(x, 0, z) \exp \left[ -\int_0^d \kappa(\lambda)c(x, y, z, t) \, dy \right] \int_x^z c(x, y, z, t) \, dy \, dz
\]

If absorption is weak,\(^{18} \) as is assumed throughout this article, the exponential function can be approximated by the first two terms in its Taylor’s series expansion. On this basis, the instantaneous absorbance \( A(t) \), i.e. the log (base 10) of the ratio of the light intensity incident on, and that emerging from the cell, is expressed by Equation (4):

\[
A(t) = \frac{\int_x^z I(x, 0, z) \varepsilon(\lambda) c(x, y, z, t) \, dy \, dz}{\int_x^z I(x, 0, z) \, dy \, dz}
\]

Equation (5)

\[
A(t) = \varepsilon \int_0^d c(y, t) \, dy
\]

where the explicit dependence of \( \varepsilon \) on \( \lambda \) will, hereafter, be omitted. This expression specifies that the intensity of the light emerging from the cell is proportional to the integral of the concentration profile along \( y \), and would be applicable for measurements in which a beam of light is incident normal to a semitransparent, planar electrode placed in the \( xz \) plane (Figure 1a). Alternatively, the beam could propagate through the solution and reflect off the surface of a highly polished electrode at an angle strictly smaller than 90° (Figure 1b). This geometry will increase the effective optical path compared to the transparent
where \( n_{12} = n_2/n_1 \). If \( n_2 < n_1 \) and \( \sin \phi_1 > n_{12} \), \( \phi_1 \) becomes imaginary leading physically to a condition known as total internal reflection.\(^{16}\) Based on purely trigonometric arguments, Equation (6) can be rewritten as

\[
\cos \phi_1 = \pm i \frac{\sin^2 \phi_1}{n_{12}^2} - 1
\]

(7)

Based on Equations (6) and (7), the amplitude of the electric field, \( E \), may be shown to be proportional to Equation (8):

\[
e^{-i\omega((\sin^2 \phi_1)/(n_{12}^2))} e^{-i(\omega t)/(n_{12}^2)} \sqrt{\sin^2 \phi_1/(n_{12}^2)}-1
\]

(8)

where \( \omega = 2\pi v_j/\lambda_1 \) and \( v_j \) and \( \lambda_1 \) are the velocity and wavelength of light in medium \( j \), respectively. This expression represents a wave travelling along the \( x \)-axis within the interfacial plane, for which its intensity decreases exponentially along the \( y \)-axis, i.e. normal to the plane. The distance at which the magnitude of the electric field \( E \) decreases to \( 1/e \) of its value at the precise interface is known as the depth of penetration \( \delta \) (Equation 9):

\[
\frac{E_0}{E_\delta} = \frac{1}{e} = e^{-i(\omega \delta)/(\lambda_1)} \sqrt{\sin^2 \phi_1/(n_{12}^2)}-1
\]

(9)

Hence, in terms of \( \omega = 2\pi v_j/\lambda_1 \),

\[
\delta = \frac{\lambda_2}{2\pi \sin^2 \phi_1/n_{12}^2} = \frac{\lambda_1}{2\pi \sqrt{\sin^2 \phi_1 - n_{12}^2}}
\]

(10)

where \( \lambda_1 = n_{12}\lambda_2 \) in Equation (10).

This evanescent wave can be used to probe species present at, and in the near vicinity of the interface, as has been widely popularized in the infrared spectral region under the acronym of attenuated total reflection (ATR).\(^{19}\) It thus follows from Equation (10) that \( \lambda \) and \( \delta \) are of the same order of magnitude, i.e. a few hundred nanometers in the UV/VIS region.

### 2.2 Mass Transport

#### 2.2.1 Quiescent Solutions

In the absence of complications derived from ionic migration in an electric field, natural convection, and homogeneous chemical reactions, mass transport in stagnant solutions is governed to a good degree of approximation by Fick’s second law,\(^{20}\)

\[
\frac{\partial c}{\partial t} = D \nabla^2 c
\]

(11)

where \( D \) is the diffusion coefficient of the species in question. The symbol \( \nabla^2 \) in Equation (11) represents the...
Laplace, which in cartesian coordinates is given by Equation (12):

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$$

(12)

For measurements performed over relatively short periods of time, as is often the case, the changes in concentration of reactants and products are confined to a small volume of solution close to the electrode surface. Under these conditions, the composition of the media far away from the electrode may be assumed to remain unaltered during the entire data acquisition period, and thus the actual size of the container may be regarded as being arbitrarily large.

The theoretical treatment of a vast number of UV/VIS spectroelectrochemical experiments involving planar, cylindrical and spherical electrodes reduces to finding solutions of Equation (11) in one dimension under the initial and boundary conditions specified in the left column of Table 1, where $C_R$ is the concentration of an electroactive reactant R, and the superscript 'o' represents its bulk value. As will be illustrated for a few simple cases in this article, the Laplace transform method(21) affords a particularly powerful tool for solving problems of this type. (15,22)

It is convenient from a computational viewpoint to define a dimensionless concentration, i.e.

$$\theta_R(y, t) = \frac{C_R(y, t) - C_R}{C_R^{\infty}}$$

(13)

Substitution of Equation (13) into Equation (11) renders a similar differential equation subject to initial and boundary conditions shown in the center column in Table 1, which do not depend explicitly on the value of $C_R^{\infty}$.

Subsequent application of the Laplace transform with respect to $t$ reduces the problem to solving a simple linear differential equation, as prescribed in the third column in that same table, for which a solution can be easily obtained to yield

$$\tilde{\theta}_R(y, s) = \tilde{\theta}_R(0, s)e^{-\left(\sqrt{s/D_R}\right)^2y}$$

(14)

In Equation (14) the bar above indicates that the function has been Laplace transformed, and $\tilde{\theta}_R(0, s)$ is the concentration of the reactant at the boundary for $t > 0$ in Laplace space. As will be shown, the quantitative analysis of a variety of electrochemical techniques requires for $\tilde{\theta}_R(0, s)$ to be explicitly specified.

Many of the systems to be described in this article involve simple reactions of the Equation (15) type:

$$R \rightarrow P$$

(15)

where, unless otherwise stated, both R and P are solution phase species. A relationship between the concentration profiles of R and P can be obtained from conservation of mass at the surface (Equation 16)

$$D_R \frac{\partial C_R(y, t)}{\partial y} \bigg|_{y=0} = -D_P \frac{\partial C_P(y, t)}{\partial y} \bigg|_{y=0}$$

(16)

The terms on the right and left of this equation represent the fluxes of P and R through the electrode, respectively, bearing opposite signs, as required.

2.2.1.1 Chronocoulometry Consider a planar electrode embedded in the $xz$ plane immersed in a quiescent, homogeneous solution containing an electrochemically active species R, and assume a potential step is applied to the electrode of a magnitude large enough to reduce $C_R$ to zero at the surface. This experimental protocol constitutes the basis of chronocoulometry, an electrochemical technique in which the current generated following the potential step is monitored as a function of time. The time evolution of the concentration profile for R in this case may be obtained by setting $\tilde{\theta}_R(0, t) = 1$. Inserting its Laplace transform, $\tilde{\theta}_R(0, s) = 1/s$, in Equation (14) gives Equation (17),

$$\tilde{\theta}_R(y, s) = \frac{1}{s} e^{-\left(\sqrt{s/D_R}\right)^2y}$$

(17)

which yields Equation (18) upon Laplace inversion:

$$C_R = C_R^{\infty} \text{erf} \left( \frac{y}{2\sqrt{D_R}t} \right)$$

(18)

where erf($z$) is the error function of argument $z$. (23)

</tbody>
</table>
A series of $C_R/C_R^0$ versus $y$ plots show that for fixed values of $t$, the concentration near the surface is proportional to the distance from the electrode (Figure 2). Linear extrapolation to the bulk concentration, i.e. $C_R/C_R^0 = 1$, as indicated in that figure defines an imaginary region known as the Nernst diffusion layer. This simple diffusion theory predicts that, as time elapses, the thickness of this layer $\delta_N$ extends progressively into the bulk solution. In practice, however, variations in concentration give rise to differences in the density of the media, and thus to the onset natural convection, a phenomenon not considered by Fick’s second law, leading ultimately to the formation of a rather static boundary layer.\(^{(24)}\)

If the product of the reaction $P$ is not present at the beginning of the experiment, its time-varying concentration profile can be calculated in a very similar way by defining an appropriate dimensionless concentration (Equation 19),

$$\theta_p(y, t) = -\frac{C_p}{C_p^0}$$

rendering a problem identical to that specified for $R$ in Table 1. In Laplace space this gives Equation (20),

$$\tilde{\theta}_p(y, s) = \tilde{\theta}_R(0, s)e^{-s/D_p y^2/2}$$

where $\tilde{\theta}_R(0, s)$ is the dimensionless concentration of $P$ at the electrode surface. The latter can be obtained from Equation (16) in Laplace space, as the additional boundary condition, which in terms of dimensionless concentrations reads

$$\tilde{\theta}_p(0, s) = -\tilde{\theta}_R(0, s)\left(\frac{D_R}{D_p}\right)^{1/2}$$

Insertion of Equation (21) into Equation (20) and replacing $\tilde{\theta}_R(0, s)$ by $1/s$ yields Equation (22),

$$\tilde{\theta}_p(y, s) = -\frac{1}{s}\left(\frac{D_R}{D_p}\right)^{1/2}e^{-s(D_R/D_p)^{1/2}y}$$

which upon subsequent Laplace inversion gives the time-dependent concentration profile of $P$ for a chronocoulometric-type experiment (Equation 23):

$$C_p(y, t) = \left(\frac{D_R}{D_p}\right)^{1/2}C_p^0\text{erfc}\left(\frac{y}{2\sqrt{D_p t}}\right)$$

where $\text{erfc}(z) = 1 - \text{erf}(z)$ is the complementary error function of argument $z$\(^{(23)}\).

An explicit expression for the flux of $P$ at the surface can be obtained from Equation (20) as Equation (24),

$$-D_p\frac{\partial \tilde{\theta}_p(y, s)}{\partial y} = \sqrt{D_p s}\tilde{\theta}_p(0, s)$$

a quantity proportional to the charge that flows across the electrode per unit time due to a heterogeneous electron transfer reaction, or faradaic current.

The total amount of material produced by the electrode reaction up to time $t$ is then proportional to the integral of the flux with respect to $t$, which in Laplace space is equivalent to simply dividing Equation (24) by $s$, to yield a quantity denoted as $Q(s)$.

$$Q(s) = \sqrt{D_p s} \tilde{\theta}_p(0, s)$$

Equation (25) is also obtained by integrating the dimensionless concentration profile along the entire $y$-axis, a quantity proportional to the absorbance (see Equation 5), provided $P$ is the only absorbing species in the media (Equation 26):

$$\int_0^\infty \tilde{\theta}_p(y, s) dy = \int_0^\infty \tilde{\theta}_p(0, s)e^{-s(D_R/D_p)^{1/2}y} dy = \sqrt{D_p s} \tilde{\theta}_p(0, s)$$

Such an identity should not be surprising, as the total amount of solution-phase material produced by the electrode, is indeed directly proportional to that calculated based on the flux at the interface. However, no such rigorous relationship exists involving the measured charge, as in many cases the current may contain nonfaradaic contributions derived primarily from interfacial double layer capacitive effects.

2.2.1.2 Coupled Chemical Reactions Many electrochemical processes of fundamental and technological interest involve generation of species that are
either intrinsically unstable, i.e. undergo spontaneous decomposition, or are capable of reacting with other solution-phase species. The latter include redox-mediated catalysis in which reduction or oxidation of the reactant R at an electrode produces P (Equation 27), which in turn reacts with Q via homogeneous electron transfer to yield a desired product Z, regenerating R (Equation 28):

\[
\begin{align*}
R & \rightarrow P \quad (27) \\
P + Q & \rightarrow Z + R \quad (28)
\end{align*}
\]

A mathematical analysis of this reaction sequence requires that the appropriate diffusion equations for R and P are solved simultaneously. Under conditions in which there is great excess of Q in solution, the homogeneous electron transfer reaction may be assumed to be pseudo first order in P. Furthermore, if both Q and Z are electrochemically inactive in the potential range in which R is either oxidized or reduced, the system of differential equations governing the overall process may be shown to be given by Equations (29) and (30),

\[
\begin{align*}
\frac{\partial C_R}{\partial t} &= D_R \nabla^2 C_R + \beta^2 C_P \quad (29) \\
\frac{\partial C_P}{\partial t} &= D_P \nabla^2 C_P - \beta^2 C_P \quad (30)
\end{align*}
\]

where $\beta^2 = kC_Q$ is a pseudo-first-order rate constant. A solution to the concentration step problem for P in Laplace space, assuming $D_R = D_P = D$, may be obtained by the same techniques introduced above, yielding Equation (31):

\[
\tilde{\theta}_P(y, s) = e^{-[(s + \beta^2)/D]^{1/2}y}
\]

where $\tilde{\theta}_P(y, s) = \mathcal{L}_P/C_R$ and $\mathcal{L}_P$ is the Laplace transform of $C_P$.

### 2.2.2 Diffusion in the Presence of Convective Flow

The relationship that governs convective diffusion of solution-phase species that do not participate in any homogeneous phase reactions may be written in general as Equation (32):

\[
\frac{\partial c}{\partial t} = D \nabla^2 c - \nabla c
\]

where $\mathbf{v}$ is a vector that represents the fluid velocity. Considerable mathematical simplifications to this rather formidable problem can be obtained provided that two conditions are fulfilled:

1. The thickness of the diffusion boundary layer must be small compared to the thickness of the hydrodynamic boundary layer, i.e. that region of the solution in which velocity gradients occur, so that the velocity components along the relevant axes can be approximated by the first terms of their power series expansion along an axis normal to the electrode surface.

2. Convective, rather than diffusion, is the predominant mode of mass transport along the axis parallel to the electrode surface in the direction of fluid flow.

Under the same conditions specified for diffusion in quiescent media (section 2.2.1), the convective diffusion equations for a rotating disk (and ring-disk), channel-type, and tube-type geometries under steady state are given by Equations (33) in Table 2, yielding Equations (40) and (41):

\[
\begin{align*}
s \tilde{\theta}(s, Y) &= \frac{1}{Y} \frac{\partial^2 \tilde{\theta}(s, Y)}{\partial Y^2} \quad (40) \\
\lim_{Y \to \infty} \tilde{\theta}(s, Y) &= 0 \quad (41)
\end{align*}
\]

where $L_X[\theta(X, Y)] = \tilde{\theta}(s, Y)$

The general solution to this problem may be written as Equation (42),

\[
\tilde{\theta}(s, Y) = A_1(s) \text{Ai}(s^{1/3}Y) \quad (42)
\]

where $\text{Ai}(z)$ is the Airy function of argument $z$.

At $Y = 0$ Equation (43) holds

\[
\tilde{\theta}(s, 0) = \frac{A_1(s)}{3^{1/3}\Gamma(2/3)} \quad (43)
\]

Hence, $A_1(s) = 3^{2/3}\Gamma(2/3) \tilde{\theta}(s, 0)$, and therefore,

\[
\tilde{\theta}(s, Y) = 3^{2/3}\Gamma \left( \frac{2}{3} \right) \tilde{\theta}(s, 0) \text{Ai}(s^{1/3}Y) \quad (44)
\]

From Equation (44), and recalling Equation (45),

\[
\frac{\partial \text{Ai}(s^{1/3}Y)}{\partial Y} \bigg|_{Y=0} = -\frac{3^{-1/3}}{\Gamma(1/3)} s^{1/3} \quad (45)
\]

the flux at the surface is given by

\[
\frac{\partial \tilde{\theta}(s, Y)}{\partial Y} \bigg|_{Y=0} = -3^{1/3} \frac{\Gamma(2/3)}{\Gamma(1/3)} \tilde{\theta}(s, 0) s^{1/3} \quad (46)
\]
and then replaced into Equation (44) to yield Equation (48):

\[
\tilde{\theta}(s, Y) = -3^{1/3} \Gamma(1/3) \frac{\tilde{\varphi}(s, Y)}{\Gamma(2/3)} Y^{-1/3} \tilde{\theta}(s, Y) \quad s^{-1/3} \tag{48}
\]

Equations (44) and (46–48) and their corresponding inverse Laplace transforms (see Table 3) provide useful relationships between fluxes and concentrations, which can be used to solve a variety of complex problems of electrochemical and spectroelectrochemical interest.

### 3 EXPERIMENTAL CONSIDERATIONS

Spectroelectrochemical experiments in the UV/VIS range may be broadly classified as transmission, external reflection, and internal reflection (see Figure 1). This brief section summarizes general aspects of these measurements with particular emphasis on factors that limit their capabilities in terms of spatial and temporal resolution, as well as detection sensitivity. More specialized issues are discussed in the applications section.

With the exception of the thin layer technique in the static mode, for which cells can be readily adapted to fit in the sample compartment of commercial spectrophotometers, implementation of all other UV/VIS spectroelectrochemical methodologies requires the custom assembly of optical components to bring radiation...
into the cell and, after interaction with the electrolyte solution, redirect the beam to the detection stage.

The spatial resolution of profile images is governed primarily by diffraction limits imposed by the optics, which set bounds to how small a volume can be reliably imaged, about 2–4 μm for this type of application, although in some cases the size of individual pixels or diodes in arrays may become the limiting factor. Beam collimation, an important aspect of this type of experiment, can be most readily achieved with lasers. However, wavelength tunability may at times be required and, in the absence of expensive instrumentation such as tunable solid-state and dye lasers, conventional optical components can be utilized to modify beams from arc or filament lamps into the desired shape. Even when collimation is optimum, a beam traveling parallel and too close to the electrode surface will undergo diffraction. Although analysis of the pattern generated is closely related to the profile itself, it has been difficult to obtain reliable quantitative spatial information using this approach. Advantage has been taken, however, of the spatial specificity of the diffracted beam to probe a small volume of solution, within less than 10 μm from an electrode surface especially for transient type measurements.

Technical advances in electronics have rendered electrochemistry (more precisely, the ability to establish a specific working electrode potential over a short period of time) as the factor that limits time-resolution, rather than data acquisition. Conventional potentiostats suffer from serious limitations, in that the powers required to achieve potential control are higher than the compliance limits of regular operational amplifiers. For example, if a 0.5 V step is applied to an electrode with a double layer capacity of 1 μF, over a period of 1 μs, the potentiostat must supply a current of 0.5 A. If, in addition, the resistance due to the electrolyte is of about 0.5 kΩ, the voltage required to drive the system would be 250 V, or a peak power of 125 W.

A means of overcoming some of these restrictions, implemented by Winograd, involves the use of a capacitor to inject charge into the double layer at very fast rates, coupled to a potentiostat, to establish potential control at a later time. Further reductions in the time constant of the cell capacitance, defined as the product of the cell resistance and the cell capacitance, can be achieved using microelectrodes. Their size leads to smaller currents and, thus, reduced power requirements. This strategy allows use of a two-electrode cell arrangement with a comparatively much larger counter electrode, so that its potential may not be greatly affected following the potential step. Using this approach, charge can be delivered to the working electrode over tens of nanoseconds. It is indeed serendipitous that UV/VIS spectroelectrochemical methods have played a key role in verifying that potentials can indeed be controlled over such short periods of time.

Detection sensitivity is determined by the response of the photomultiplier, photodiode or charge-coupled device (CCD), including their noise characteristics. Most often, signal averaging or modulation schemes are required to extract signals for systems involving species displaying small molar absorptivities at low concentrations, or cells with thin pathlengths. Although double-beam instruments have been used for UV/VIS spectroelectrochemical studies, it is usually not possible to employ a reference beam to normalize absorption from the cell. Under such conditions, special efforts must be made to stabilize the single beam by using, for instance, a split beam in conjunction with its own photomultiplier to control the voltage at the primary photomultiplier.

A powerful experimental approach to enhancing sensitivity via signal averaging involves the use of spectrophotometers capable of acquiring spectra over a wide wavelength region in times of the order of milliseconds. Some of these instruments are based on mechanical motion, such as the vibrating grating/mirror developed by Harrick, the ingenious ScanDisk of OLIS’s subtractive monochromator, or on the use of CCD such as that described by Park. Wavelength modulation provides yet another viable means of extracting very weak spectral signals. This technique relies on the application of a periodic perturbation to the wavelength by, for example, mechanically vibrating a grating or a slit. Hence, using a conventional lock-in amplifier it becomes possible to measure a signal proportional to the derivative of the response, which can then be integrated to generate, within an additive constant, a more conventional spectrum. Another type of signal averaging involves single wavelength measurements in which the same experiment is performed repetitively. Implementation of this methodology relies on returning the system to its original state following each acquisition over as short a time as possible. Such conditions are most readily achieved by probing volumes of solution very close to the electrode surface using, for example, internal reflection or diffraction, which can be “filled” and “dumped” by potential control.

Because of differences in the acquisition times and other considerations, it is difficult to assess absolute sensitivities of the various techniques developed to date. Nevertheless, a very useful semiquantitative comparison of these methods has been provided by McCreery et al.

4 APPLICATIONS

This section presents experimental and theoretical aspects of the techniques that constitute the foundations of
modern UV/VIS solution-phase spectroelectrochemistry. The intent has not been to review exhaustively the literature in this area, but rather to provide illustrative examples that may be used as a basis for the design and execution of experiments and interpretation of data.

The material selected has been organized in increasing order of complexity, which coincides, by and large, with their chronological development. In this spirit, the first subsection introduces the now classical thin-layer cell technique in the static mode, a method that provides primarily thermodynamic and kinetic information of strictly solution-phase reactions, followed by dynamic measurements in quiescent media involving optically transparent electrodes. Attention is then focused on the monitoring of solution composition changes in the immediate vicinity of the electrode by internal reflection, and of the entire diffusion layer by the more powerful and versatile specular reflection mode. This latter approach enhances the detection sensitivity by increasing the effective optical path allowing, in addition, use of a much wider variety of electrode materials. Illustrations of reflection techniques are provided for a number of electrode geometries, including microelectrodes, under stagnant and forced convection conditions. Described in the subsequent section are imaging techniques to obtain detailed dynamic information regarding evolution of concentration profiles using mostly multidiode array detectors. Owing to its own mathematical nuances, steady and transient UV/VIS spectroelectrochemical methods under forced convection were grouped in a separate subsection. Finally, the last subsection addresses methods that rely on potential modulation for the study of kinetics and mass transport phenomena associated with electron-transfer reactions.

Because of their unique spectroscopic and electrochemical properties, a few systems have been used as models for the development of most of these techniques. The most useful absorption features and the corresponding diffusion coefficients of some of the most representative species involved are compiled in Table 4.

### 4.1 Transmission Thin-layer Spectroelectrochemistry

The simplest type of UV/VIS spectroelectrochemical experiment, both from experimental and theoretical viewpoints, involves measurements of fully homogeneous solutions that contain a single species that absorbs light in this spectral region, either a redox-active reactant or a product generated directly or indirectly by an electrochemical process. Such conditions can be achieved by using the electrode as a source or sink of electrons to convert reactants into products to the desired extent, rendering a solution for which the concentration of all species is uniform within the thin layer cell and in equilibrium with the applied potential. On this basis, the absorbance may be interpreted in the same fashion as in conventional nonelectrochemical spectroscopic measurements.

Owing primarily to their ease of construction, high versatility and compatibility with commercial spectroscopic instrumentation, thin-layer cells have become a common tool for thermodynamic and also for certain kinetic studies of redox-active materials containing UV/VIS chromophores. In particular, the lack of spatial dependence allows conventional kinetic analyses for determination of rate constants and reaction orders and elucidation of mechanisms.

The archetypal UV/VIS thin-layer spectroelectrochemical cell is comprised of two flat plates made out of a material transparent in this wavelength range, such as fused silica or quartz, placed parallel to and at a small distance from each other (10–200 µm) forming a small volume cavity. Either a thin metal, or a conductive oxide layer, such as In-doped Sn oxide, deposited on one of the plates, or a thin self-standing open metal grid interposed between the plates is used as the optically transparent working electrode. Structural integrity and isolation from the ambient atmosphere are achieved by means of adhesives, gaskets or mechanical compression. Depending on the design, the cell can be filled by suction or by capillary action through an opening at the bottom in contact with a bulk solution reservoir, where the reference and auxiliary electrodes are placed (Figure 3). Various types of optically transparent thin-layer electrode (OTTLE) cells have been designed to fit in the sample compartment of conventional spectrophotometers enabling transmission spectroelectrochemical data to be acquired normal to the electrode in a rather straightforward fashion.

Vast improvements in the spectral sensitivity of thin layer cells can be obtained by placing the beam parallel as opposed to normal to the electrode surface, thereby

### Table 4 Molar absorptivities at the specified wavelengths and diffusion coefficients for selected chromophores commonly used in spectroelectrochemical experiments
increasing the optical pathlength, a configuration that also allows the use of nontransparent electrodes. At least two versatile long optical pathlength thin-layer cells (LOPTLCs) have been described in the literature using either conventional windows\(^43\) (Figure 4) or arrays of optical fibers\(^44\) to bring the beam in and out of the cell.

Among its many advantages, transmission thin layer spectroelectrochemistry enables expedient and quantitative conversion of reactant into products, which in many cases may be difficult to synthesize, handle or stabilize over long periods of time. In addition, the small area of contact between the solution in the thin layer and that in the bulk reservoir increases the time required to achieve chemical equilibration. In other words, the composition of the solution within the layer following polarization remains virtually unaltered after the electrode is open circuited for periods of time on the order of minutes. As the electrolyte solutions are at all times homogeneous, the absorbance in Equation (5) reduces to the most familiar form of Beer’s law, allowing the spectral properties of electrogenerated species to be determined.

However, the thin character of the cell brings about large ohmic resistances. Consequently, the time required for a uniform potential to be established within the cell can be relatively long, thereby restricting the range of accessible homogeneous rate constants that can be measured with this technique. In fact, about 30 s are often required for complete electrolysis of material confined within the OTTLE cell.

Despite these shortcomings, transmission UV/VIS spectroelectrochemistry has become a well-established tool in inorganic chemistry and biologically oriented areas for the characterization of redox-active species under equilibrium conditions, or for reactions that proceed via fast electrochemical steps followed by a relatively slower chemical step. Examples of some of these applications are given below.

4.1.1 Thermodynamics

4.1.1.1 Determination of the Formal Reduction Potential \(E^{\circ}\) and the Number of Electrons Transferred \(n\) for Redox Reactions Involving Stable Solution-phase Species

Consider a generalized reversible redox couple (Equation 49)

\[
R + ne^- \rightleftharpoons P
\]  

(49)

where both \(R\) and \(P\) represent stable solution phase species, for which the kinetics of electron transfer for
both the forward and reverse process are relatively fast. Under these conditions, the ratio of the concentrations of R and P at the electrode–solution interface will be determined by the applied potential \( E_{\text{appl}} \), via the Nernst equation. If the electrode is polarized at a fixed value of \( E_{\text{appl}} \) for a sufficiently long time, so that \( C_R \) and \( C_P \) become uniform throughout the region probed by the beam, an explicit relationship can be obtained between \( E_{\text{appl}} \) and the relative concentrations of R and P (Equation 50):

\[
E_{\text{appl}} = E^o' + \frac{RT}{nF} \ln \left( \frac{C_R}{C_P} \right)
\]

(50)

where \( E^o' \) is the formal reduction potential of the redox couple.

If it is further assumed that at least one of these species displays one or more clearly defined features in the UV/VIS region, it becomes possible to determine \( C_R/C_P \) as a function of \( E_{\text{appl}} \) directly from the spectroscopic data, i.e.

\[
\frac{C_R}{C_P} = \frac{A_i - A_P}{A_i - A_1}
\]

(51)

In Equation (51) \( A_P \) and \( A_1 \) are the absorbances due to P and R, respectively, at judiciously selected wavelengths, measured at potentials sufficiently positive or negative so that only P or R are present in the solution, and \( A_i \) is the corresponding absorbance at some intermediate \( E_{\text{appl}} \) value. Combination of Equations (50) and (51) yields Equation (52)

\[
E_{\text{appl}} = E^o' + \frac{RT}{nF} \ln \left( \frac{A_i - A_P}{A_i - A_1} \right)
\]

(52)

from which \( E^o' \) and \( n \) can be determined, respectively, from the intercept and slope of \( E_{\text{appl}} \) versus \( (A_i - A_P)/(A_i - A_1) \), or Nernstian plots. The subsections to follow will show examples of application of these principles.

Reversible Systems. Figure 5 shows in situ UV/VIS spectra of a 2.0 mM \( K_3[Fe(CN)_6] \) aqueous solution in 1 M KCl at different potentials in the range -0.5 (a) and 0.0 (h). The inset shows a plot of \( E_{\text{appl}} \) versus \( \log(C_R/C_P) \) at (●) \( \lambda = 312 \) nm and ( ) \( \lambda = 420 \) nm obtained in a thin-layer cell. Clear evidence that this reaction proceeds via two consecutive one-electron transfer steps was obtained by Mark et al.\(^{46,47}\) in buffered solutions (pH = 6.86), using an Hg–Au minigrid working electrode in an OTTLE cell. For these measurements, the potential was stepped to different values in the range \(-1.15 < E < -0.1 \) V versus SCE (saturated calomel electrode) and the UV/VIS spectrum recorded after equilibrium had been established. Two distinct absorption peaks were observed for potentials in the range \(-0.58 < E < -0.75 \) V at 311 and 361 nm (Figure 7a), and \(-0.77 < E < -0.95 \) V versus SCE (Figure 7b) at 368 nm. Nernstian plots of the absorbance measured at these wavelengths yielded for the two one-electron transfer processes values of \( E_{1/2} = -0.655 \) V and \( E_{1/2} = -0.88 \) V versus SCE.

Mediated Electron Transfer. The rates of heterogeneous electron transfer of large redox-active molecules,
such as proteins, are very small, due at least in part to the insulating character of the chemical environment surrounding the redox site. A common strategy to overcome this difficulty, shown schematically in Scheme 1, is to employ an electron-transfer mediator M, either in solution or bound to the electrode surface, capable of exchanging electrons with such larger molecules in solution at much higher rates.

This approach enables spectra of redox-active proteins or other large molecules to be recorded as a function of $E_{\text{appl}}$, allowing values of $E^0$ and $n$ to be determined by the same method described above. A classic example of this principle is provided by cytochrome c, a species that exhibits no clear voltammetric features on Au electrodes. However, large enhancements in the electron transfer rates can be obtained by using 2,6-dichlorophenolindophenol (DCIP) as a mediator, as shown in Scheme 2.
This mediated process was monitored spectroelectrochemically in phosphate buffer (pH 7), using a Au minigrid working electrode in an OTTLE cell, at potentials in the range −0.600 (fully reduced cytochrome c) to 0.300 V (fully oxidized cytochrome c) (Figure 8). Nernstian plots for absorbance measured at 520 and 550 nm, the characteristic absorption maxima for cytochrome c(oxidized) and cytochrome c(reduced), yielded values of $E^\circ = +0.264$ V versus SHE and $n = 1$.

4.1.2 Coupled Chemical Reactions

Electrochemistry provides an expedient means of preparing solutions of a given composition by controlling the charge that flows through the interface over a certain period of time. It thus becomes possible to use this method to monitor rates of some chemical reactions involving electrogenerated species under various initial conditions as a function of time. Application of this simple methodology assumes that the total time of charge injection is long enough for the concentration of all species to be uniform throughout the thin-layer cell before any significant bulk reaction occurs.

This approach has been exploited for studies of certain inorganic and biological processes that proceed via complex mechanisms, including chemical reactions that precede or follow an electron-transfer step (Scheme 3), for which one of the species involved absorbs light in the UV/VIS range.

$$\text{R} + ne^- \rightarrow \text{P}$$

$$\text{P} \rightarrow \text{Q}$$

Scheme 3

Three different techniques will be featured in this section to illustrate the principles involved.

4.1.2.1 Single Potential Step Perhaps the simplest transient spectroelectrochemical experiment of the type discussed above involves monitoring the absorbance of one or both of the redox species as a function of time following a potential step. An excellent illustration of this technique is provided by the work of Owens and Dryhurst, who studied the electrochemical oxidation of 5,6-diaminouracil in aqueous buffered solutions pH 4–6, for which the product, the corresponding diimine, undergoes hydrolysis, as depicted in Scheme 4. This system may be regarded as a model for a variety of biologically fundamental redox processes, including the enzymatic oxidation of purines.

UV/VIS spectra obtained using an OTTLE cell incorporating a Au minigrid electrode, recorded at different time intervals after the potential step was applied, revealed a broad band centered at 320 nm (not shown here) attributed to the diimine intermediate. If it is assumed that the decomposition of diimine follows first-order kinetics, the time dependence of its decay can be related to the change in absorbance via Equation (53):

$$\ln\left(\frac{A_t}{A_0} - A_\infty\right) = -kt + \ln\left(\frac{A_0 - A_\infty}{A_0}ight)$$

where $A_0$, $A_t$, and $A_\infty$ are the absorbances at times 0, $t$ and at the end of the experiment. A linear relationship...
**Figure 9** (a) Absorbance versus time recorded at $\lambda = 320$ nm during the electrooxidation of 10 mM 5,6-diaminouracil in McIlvaine buffer (pH 5) at 0.35 V in a thin-layer cell with an Au minigrid electrode. The arrow indicates the time at which 5,6-diaminouracil was fully electrolyzed. (b) Plot of $t$ versus $\log(A - A_\infty)$ obtained from the data in (a) by setting $t = 0$, at the point specified by the arrow.\textsuperscript{49}

was observed between $t$ and $\ln(A_1 - A_\infty)$ recorded at $\lambda = 320$ nm (Figure 9), from which the rate constant $k_1$ was calculated, yielding a value of 0.04 s$^{-1}$ at pH = 4.

### 4.1.2.2 Double Potential Step

A slight variation of the method just described involves application of a second potential step, after allowing a period of time $t_R$ to elapse following the initial potential step. Assume, for example, that a certain absorbing species produced during the initial step, is then partially consumed via a first-order chemical reaction as specified in Scheme 3 above. If a potential step is applied in precisely the opposite direction at $t_R$, so as to convert all remaining P back to R, the difference in the change in absorbance between the first, $\Delta A_f$ (proportional to the amount of P generated), and the second step, $\Delta A_b$ (proportional to the amount of P remaining in solution), provides a measure of the amount of product decomposed during $t_R$. Based on information collected for various values of $t_R$, the rate of chemical decomposition of the product can be determined from Equation (54):

$$\ln \frac{\Delta A_f}{\Delta A_b} = k t_R$$ \hspace{1cm} (54)

This method was employed to determine $k_f$ for benzidine rearrangement\textsuperscript{50} in an aqueous acidic electrolyte, a process that proceeds via the electrochemical–chemical (EC) mechanism shown in Scheme 5, using an Au minigrid electrode in an OTTLE cell.

For these experiments, azobenzene was first completely reduced to hydrazobenzene during the first potential step from 0.0 to $-0.6$ V versus SCE, the potential was then maintained at $-0.6$ for a reaction time $t_R$, and the remaining hydrazobenzene reoxidized to azobenzene during the second potential step to 0.3 V. All spectroscopic data were acquired at $\lambda = 325$ nm, a value at which only azobenzene displays significant absorption. Typical optical response curves are shown in Figure 10, and the plot based on Equation (54) is given in Figure 11.

The advantage of the double-potential step versus single-potential step method is that either P or R can be monitored spectroscopically. However, the results obtained with this approach are less precise than for

single potential step, as \( t_R \) has to be calculated graphically (dotted lines in Figure 10).

4.1.2.3 Single Potential Step Open Circuit Relaxation

In some cases, species P in Scheme 3 can yield upon subsequent chemical reaction an electroactive species Q, which might be the original electroactive reactant R itself, a factor that can complicate analysis of spectroscopic data of the type introduced in previous sections. If \( k \) in Scheme 3 is sufficiently small, it becomes possible to monitor the reaction progress by bringing the electrochemical reaction to completion and then opening the electrical circuit enabling P to undergo further chemical transformations. This technique, known as single potential step open circuit relaxation, has been used to elucidate the mechanism of oxidation of the psychoactive drug CPZ.\(^{[51]}\) This material can be electrochemically oxidized in strongly acidic media via two sequential one-electron steps to produce first, a deep red cation radical chlorpromazine cation radical (CPZ\(^{+*}\)) (see Table 4), and, at more negative potentials, a colorless sulfoxide-type derivative (CPZO). However, the cation radical undergoes disproportionation according to the reaction sequence shown in Scheme 6.

\[
\text{Electrode: CPZ} \rightarrow \text{CPZ}^{+*} + e^- \\
\text{Solution: } 2 \text{CPZ}^{+*} + \text{H}_2\text{O} \xrightarrow{k} \text{CPZ} + \text{CPZO}
\]

Scheme 6

For this process, Q in Scheme 3, happens to be identical to R. Evidence in support of this mechanism was obtained by spectroelectrochemical experiments using an Au minigrid working electrode in an OTTLE cell in a strongly acidic solution. Figure 12 shows a series of spectra recorded for a potential step from 0.250 V to 0.620 mV versus SCE. Curves a and b in this figure represent spectra collected before (CPZ) and after the step allowing 2.8 min for equilibrium to be reached, whereas all other spectra were recorded after the circuit was opened. The peaks at 262 and 525 nm, characteristic of CPZ\(^{+*}\), decreased during open circuit, and new features appeared at 292 and 337 nm, attributed to the final reaction product CPZO.

Plots of \( 1/C \) versus \( t \) for absorbance measured at 525 and 337 nm were linear, and therefore consistent with a

Figure 12 UV/VIS spectra recorded during a thin-layer chronoadsorptometry experiment with open-circuit relaxation in a 4.8 mM CPZ in 3 M H\(_2\)SO\(_4\): (a) spectrum of CPZ at 250 mV; (b) spectrum of CPZ at open circuit. Spectra were acquired every 2.8 min.\(^{[51]}\)
second order mechanism for CPZ decomposition, with slopes of 8.6 M$^{-1}$s$^{-1}$ and 4.4 M$^{-1}$s$^{-1}$, i.e. a ratio of 2:1, in accordance with the reaction stoichiometry.

4.1.3 Slow Scan Rate Cyclic Voltammetry

The small amount of electroactive material contained within a thin-layer cell allows changes in composition induced by the applied potential to occur within rather short times, of the order of tens of seconds. Under these conditions it becomes possible to follow optically electrochemical processes involving absorbing species, by scanning the electrode potential linearly between two prescribed limits, while monitoring the current, a technique known as cyclic voltammetry. Analysis of these measurements can be greatly simplified by scanning the potential at slow enough rates to achieve at every instant quasi-equilibrium conditions throughout the cell.

Figure 13 shows simultaneous absorbance and current data obtained on a glassy carbon electrode in the long pathlength thin layer cell (LPTLC) shown in Figure 4 in a solution of 0.4 mM ferricyanide in 0.5 M KCl at $\lambda = 420$ nm.\(^{43}\) For this LPTLC, the absorbance change, following full reduction or subsequent oxidation, is about two orders of magnitude larger than those observed for OTTLE cells described earlier.

4.1.4 Molecular Adsorption on Solid Electrodes

Advantage can be taken of the much enhanced sensitivity of LPTLC spectroelectrochemical cells and the possibility of using flat opaque electrodes to measure minute changes in concentration $\Delta C$, such as those derived from adsorption of UV/ VIS chromophores on electrode surfaces, by monitoring the corresponding decrease in the absorbance $\Delta A$. As may be inferred from simple arguments, these two quantities are related to the width of the optical cell $w$ and $\varepsilon(\lambda)$ (Equation 55):

$$\Delta C = \frac{\Delta A}{w \varepsilon(\lambda)}$$  \(55\)

On this basis, material lost from the solution phase, as measured by spectroscopic means, may be assumed to be adsorbed on the electrode surface, and the coverage $\Gamma$ may be calculated from Equation (56),

$$\Gamma = \frac{V \Delta C}{a}$$ \(56\)

where $V$ is the volume of the cell, and $a$ is the area of the electrode. The ability to measure $\Gamma$ accurately is thus determined by how small an absorbance change the instrument is capable of detecting. Saturation coverages of small size organic molecules on common metals are about $10^{-10}$ mol cm$^{-2}$; hence, assuming a cell volume of 10 $\mu$L, the change in concentration associated with formation of a full monolayer would be $10^{-5}$ M. Minimum detectable values of $\Delta A$ are of the order of 0.002 at a signal-to-noise ratio of 2; therefore, for $\varepsilon(\lambda)$ of 1000 M$^{-1}$cm$^{-1}$, $w = 1$ and $a = 1$ cm$^2$, $\Delta C$ as small as $2 \times 10^{-6}$ M, and, thus, smaller that those corresponding to $\Gamma = 1$ could be observed.

Measurements involving a series of heterocyclic aromatics were performed by Kuwana et al. with the same LPTLC spectroelectrochemical cell shown in Figure 4 incorporating a Pt electrode.\(^{52}\) Figure 14(a) shows absorbance versus time plots obtained after injecting a solution 32.9 $\mu$M $\text{trans-1,2-bis-(4-pyridine)ethylene (Pyc=Py)}$ in buffered (pH $= 7$) 0.1 M NaClO$_4$ (first curve) monitored at $\lambda = 299$ nm with the Pt electrode polarized at $-0.1$ V versus Ag/AgCl. The two other curves were obtained after a second and third injection without removing Pyc=Py adsorbed on the Pt surface during the
first injection. Figure 14(b) shows the corresponding spectra of the solution phase recorded after the absorbance had reached steady state following each injection. The very small differences observed between the second and third injections indicate that the surface had attained saturation, i.e., $\Gamma = 1$.

These data may be used to determine molecular packing densities and from these to infer the mode of bonding of species to the surface as thoroughly discussed by Soriaga and Hubbard. Proposed orientations of four of the species investigated by Kuwana et al. are shown in Scheme 7.

4.2 Transmission Spectroelectrochemistry in Semi-infinite Media

Methods based on the dynamic monitoring of absorbance changes induced by electrochemical perturbations can provide kinetic information regarding rates of homogeneous electron transfer rates involving electrogenerated species, as well as mass transport phenomena, not accessible by the static techniques described in the previous section. For simplicity, consider an OTE immersed in a solution containing a single, nonabsorbing solution-phase species $R$ capable of undergoing heterogeneous electron transfer to yield an absorbing solution phase product $P$ (Equation 57):

$$R + ne^- \longrightarrow P$$

If $C_P$ is independent of $x$ and $z$, the instantaneous absorbance $A(t)$ in Equation (4) reduces to Equation (58),

$$A(t) = \epsilon \int_0^d C_P(y, t) \, dy$$

where $d$ is the length of the optical cell along the axis of propagation of the light. Provided the measurements are made over relatively short periods of time, so that the diffusion layer thickness is always smaller than $d$, the media may be regarded as semi-infinite and $A(t)$ may be rewritten as Equation (59),

$$A(t) = \epsilon \int_0^\infty C_P(y, t) \, dy$$

or, in Laplace space (Equation 60), as

$$\mathcal{A}(s) = \epsilon \int_0^\infty \mathcal{C}_P(y, s) \, dy$$

If it is further assumed the overall measurement time is short so that no complications arise from natural convection, an explicit form for $\mathcal{C}_P(y, s)$ for a potential step experiment of the type described in section 2.2.2 may be obtained from Equation (22):

$$\mathcal{C}_P(y, s) = \frac{C_{R0}}{s} \left( \frac{D_R}{D_P} \right)^{1/2} e^{-y(D_P/D_R)^{1/2}s}$$

Equation (61) can be substituted into Equation (60) to yield Equation (62),

$$\mathcal{A}(s) = \frac{\epsilon C_{R0} D_R^{1/2}}{s^{3/2}}$$

and inverse Laplace transformed to afford an expression for the time dependence of the absorbance due to $P$ for such diffusion-controlled process (Equation 63):

$$A(t) = \epsilon C_{R0} \left( \frac{4D_Rt}{\pi} \right)^{1/2}$$

Based on the analysis of such chronoaosorptometric-type experiment, it becomes possible to determine $D_R$ if $\epsilon$ is known or, conversely, $\epsilon$ if $D_R$ is known.

A rather versatile cell design reported by Kuwana et al. suitable for this type of measurements incorporates an OTE in a glass sandwich-type cell (Figure 15), in
which the light travels along the axis of the cylinder. The small bent tube, known as a Luggin capillary, allows electrolytic contact between the main and reference electrode compartments.

Potential step chronoabsorptometry at an optically transparent tin oxide electrode has been used to study the oxidation of $[\text{Fe(CN)}_6]^{4-}$ to $[\text{Fe(CN)}_6]^{3-}$ in aqueous electrolytes by monitoring $A(t)$ at $\lambda = 420$ nm (Table 4). In accordance with theoretical predictions, plots of $A(t)$ versus $t^{1/2}$ (Figure 16) were found to be linear, yielding values of $D$ for $[\text{Fe(CN)}_6]^{3-}$ determined from the slope, of $6.5 \times 10^{-6}$ cm$^2$ s$^{-1}$, in reasonable agreement with those obtained by other methods.

One of the advantages of using large-volume cells, as opposed to thin-layer cells, is the decrease in $t_{\text{cell}}$, which leads to improvements in transient response. However, the relatively low spectral sensitivity due to the very short optical paths associated with OTE, the restricted number of electrode materials with suitable electronic and optical characteristics, and the high resistance associated with thin films, severely limit the applicability of the technique described in this section. As explored in detail later below, some of these difficulties can be overcome by implementation of dynamic methods in both internal and external reflection modes.

### 4.3 Internal Reflection

As briefly discussed in section 2.1.3, light traveling through a media of high index of refraction, impinging on a planar interface with a media of smaller index of refraction at a sufficiently large angle, will penetrate slightly into the adjacent phase and interact with species present therein. For spectroelectrochemical applications, the surface of the internal reflection element (IRE) is coated with a thin film of an electronically conducting material, such as a metal or a highly doped semiconductor, which serves as the optically transparent working electrode. This technique was pioneered by Kuwana, Winograd et al. in the 1970s.\textsuperscript{44}

The volume of solution probed by the evanescent wave is of the same order of magnitude as the wavelength of light, about 100–300 nm in the UV/VIS range, and therefore the size of the cell becomes immaterial. Under such conditions, the time response of the cell is limited not by the solution resistance, but by the thin character of the electrode, as was the case with the OTE-based techniques described in the previous sections.

Owing to the very short optical path and the relatively low concentrations of chromophores often used, the extent to which the exponentially decaying evanescent wave in the solution is attenuated is very small, and therefore its spatial dependence may be regarded as unperturbed by the presence of absorbing material therein. Under these conditions, the instantaneous absorbance is given by Equation (64),

$$A(t) = \varepsilon N_{\text{eff}} \int_0^\infty C_P(y,t) \exp \left( -\frac{y}{\delta} \right) dy$$  \hspace{1cm} (64)$$

where $\delta$ is the penetration depth (see Equation 10), and $N_{\text{eff}}$ is a sensitivity factor that depends on the geometry and electrode material.

---

**Figure 15** Sandwich cell for transmission UV/VIS spectroelectrochemical experiments.\textsuperscript{44}

**Figure 16** Plot of $A$ versus $t^{1/2}$ for the chronoamperometric oxidation of $[\text{Fe(CN)}_6]^{3-}$ at a tin oxide optically transparent electrode.\textsuperscript{54}
ULTRAVIOLET/VISIBLE SPECTROELECTROCHEMISTRY

Insertion of Equation (22) into Equation (64) in Laplace space and subsequent inversion, yields Equation (65) for a chronoabsorptometric experiment:

\[ A(t) = \frac{\varepsilon \delta N_{\text{eff}} C^0_R}{D_R} \left( \frac{D_R}{D_D} \right)^{1/2} 1 - \exp(-\beta^2 t) \text{erfc}(\beta t^{1/2}) \quad (65) \]

where \[ \beta = \frac{D_R^{1/2}}{\delta}. \]

For \( \delta \sim 100 \text{ nm} \), \( A(t) \) reaches steady state in about 1 ms, which may be regarded as the time needed to fill the cell. If the potential is then returned to its original value by applying a reverse step, the cell can be dumped over as short a time, making it possible to perform numerous identical experiments that can then be co-added and averaged to improve signal detection.

A multiple reflection internal reflection spectroscopy (IRS) cell designed by Kuwana and Winograd\(^{55,56}\) is shown in Figure 17. In this optical arrangement two prisms are used to guide the beam into and out of the IRE, allowing five internal reflections to probe the solution phase of the interface, thereby increasing the effective pathlength.

Sensitivities better than one part in \( 10^5 \) with time resolutions in the microsecond range have been obtained for systems in which \( N_{\text{eff}} \gg 1 \), and long averaging times. This is illustrated in Figure 18 for MV\(^{++} \) reduction, for which the time resolution, using charge injection to achieve fast potential control, was of the order of 4 \( \mu \text{s} \).\(^{57}\)

Advantage was taken of the extraordinary capabilities of this measurement scheme for kinetics studies involving fast processes,\(^{58}\) such as the second-order catalytic mechanism (Scheme 8) for the reaction of cyanide with electrogenerated tri-\( p \)-anisylamine cation radical (TAA\(^{++} \)) in acetonitrile.

\[
\text{TAA} \quad \text{TAA}^{++} + e^- \quad TAA^{++} + \text{CN}^- \quad 2 \text{CN}^- \quad (\text{CN})_2
\]

\[ k_1 \]

\[ k_2 \]

\text{Scheme 8}

Plots of absorbance versus time following a potential step recorded at \( \lambda = 715 \text{ nm} \), a wavelength at which TAA\(^{++} \) exhibits a characteristic absorption band, were recorded both in the presence and in the absence of tetraethylammonium cyanide (TEACN; Figure 19). Analysis of these data yielded values for the \( k_1 \) in Scheme 8 of \( 2.7 \times 10^7 \text{ M}^{-1}\text{s}^{-1} \), in agreement with those obtained by other means.

IRS also lends itself to the study of homogeneous electron-exchange reactions involving electrogenerated species for values of \( k \) in Scheme 8 larger than \( 10^6 \text{ M}^{-1}\text{s}^{-1} \). Under such conditions, the intermediate is formed in close proximity...
proximity to the electrode surface and can, therefore, be detected by the evanescent wave.

From a general perspective, quantitative analysis of experimental data can be pursued using digital simulation techniques to predict, for a proposed mechanism, time-dependent concentration profiles for all species involved, as illustrated for an electrochemical–electrochemical–chemical (EEC)-type process in Figure 20. Numerical values for the various parameters involved can then be calculated based on best fits to the experimental curves. In fact, for the reduction of MV$^{++}$ mentioned above, which has been found to follow the mechanism in Scheme 6, a fit to the data obtained by monitoring $A(t)$ at $\lambda = 605$ nm, associated with the radical cation intermediate MV$^{+*}$, yielded values of $k_f = 3 \times 10^6 \text{M}^{-1}\text{s}^{-1}$ (57).

More recently, Heineman et al. (60–63) have implemented the use of IRS to develop spectroelectrochemical sensors with high selectivity and sensitivity. For this application, the IRE is covered first with a thin conducting layer as before, and then with a film displaying molecular specificity or selective film, as shown in Figure 21. This device allows three independent sensing techniques to be employed simultaneously, i.e. electrochemistry, spectroscopy, and selective partitioning, thereby enhancing the degree of specificity for chemical detection. As a means of illustration, Figure 22 shows results obtained with simultaneous optical (panels a and b) and electrochemical techniques (panel c) for the detection of ferrocyanide partitioned into a poly(dimethyldiallyl ammonium chloride)-SiO$_2$ composite sol-gel film from an aqueous solutions at two different concentrations.

4.4 External Reflection

The rather short effective pathlengths associated with techniques based on OTEs limits their applicability to systems involving strong chromophores, or long times for sufficient absorbing material to accumulate and be detected. Although gains in sensitivity can indeed be
Figure 21 Simplified diagram of an internal reflection-based spectroelectrochemical sensor cell. ITO, indium-tin oxide.\textsuperscript{(60)}

Figure 22 Optical response at $\lambda = 420$ nm of the sensor in Figure 20 to (a) potential step and (b) cyclic voltammetry for two concentrations of Fe(CN)$_6^{3-}$. Panel 1, 0.025 mM; panel 2, 2.5 mM. Panels (c) show cyclic voltammograms recorded in those solutions recorded at a scan rate of 10 mV s$^{-1}$. Potentials are referred to an Ag/AgCl reference electrode.\textsuperscript{(60)}
achieved by IRS using extensive signal averaging, the region probed by the evanescent wave is very close to the electrode surface. Hence, it is not possible to monitor changes in composition at times longer than a few milliseconds. In addition, IRS is very sensitive to wavelength and refractive index effects on the pathlength, compromising the analysis of spectral data, particularly when $N_{\text{eff}}$ is large.

Many of these problems can be minimized by experiments in which light propagating in the solution is reflected from, as opposed to transmitted through, the electrode. This approach allows transient studies to be performed under either quiescent or convective flow conditions, involving weakly absorbing and short-lived species. Such improvements are derived primarily, but not exclusively, from increases in the optical pathlength, achieved for example by employing grazing incidence or multiple reflection, better current distribution, and from the possibility of using microelectrodes.

Implementation of external reflection geometries often requires custom assembly of components, including a light source, either a laser or a conventional arc lamp, a monochromator, a detector, and other optical elements, as prescribed by the specific application. A few optical arrangements designed for this type of spectroelectrochemical experiments are depicted in Figure 23. Considerable care has been taken to develop electrochemical cells displaying optimum optical and electrochemical response. For example, Figure 24 shows two cells reported in the literature for (a) external reflection at constant angle of incidence and (b) for multiple reflection experiments. One of the most interesting applications of external reflection, reported by McCreery et al., exploits the advantages of the small currents associated with micro-electrodes to eliminate the need for a potentiostat and use instead a capacitor-based injection circuit to charge the double layer, coupled to a pulse generator. As shown by these workers, and discussed later in this chapter, such a strategy enables a fixed electrode potential to be established following a step, within times shorter than 35 ns, making it possible to follow the time evolution of the absorbance from times as short as 0.15 µs.

Metals, even when optically polished are not perfect reflectors in the UV/VIS region; in addition, their reflectance is often a function of the state of charge and coverage of adsorbed species on the surface. However,
it is possible to either minimize, or account for these effects, allowing quantitative information to be acquired regarding the identity and reactivity of electrogenerated solution phase species produced at conventional solid electrodes.

4.4.1 Planar Electrodes

The solution-phase absorbance measured with light reflected from a planar electrode at an angle of incidence $\phi$ (Figure 24a $^{(64)}$) is $2 / \cos \phi$ larger than that observed, under otherwise identical conditions, using a beam normal to an OTE in the standard transmission configuration. The factor of 2 accounts for the beam crossing the diffusion layer twice, whereas the divisor of $\cos \phi$ reflects the increase in pathlength for a single crossing of the layer. This enhancement factor, denoted as $\eta$, arises purely from geometric considerations, assuming the electrode surface to be perfectly reflecting, and that the incident and reflected beams traverse a diffusion layer uniform along an axis normal to the surface, i.e. possible edge effects are ignored. Based on these considerations, $\eta$ will range from 2, for normal incidence, up to about 400 for $\phi$ slightly less than 89.7°. Comparisons between theoretical and experimental data, as well as quantitative calculations of edge effects, have been provided in the literature $^{(38,42,65)}$

The higher absorbances achieved at glancing incidence enable detection of short-lived electrogenerated chromophores with increased sensitivity, making it possible to monitor, for example, species with small $\varepsilon$, or strongly absorbing materials at lower concentrations. In addition, the higher electrical conductivity of massive, compared to thin film electrodes, allows measurements to be performed with better time resolution. Some of these aspects are discussed in more detail later in this section.

4.4.1.1 Identification of a Solution-phase Corrosion Product

Polarization of metals at sufficiently high potentials may result in the formation of species derived from the electrode displaying finite solubility in the electrolyte solution. An illustrative example of the use of UV/VIS spectroscopy in the external reflectance mode for the identification of a metal corrosion product was reported by Kolb et al. $^{(66)}$ for the case of Ru in acid solutions. For these experiments, a Harrick rapid scan spectrophotometer was employed to collect spectra by reflecting light from an optically smooth Ru film electrode sputtered on glass as a function of the applied potential. Figure 25 shows the normalized reflectivity of Ru polarized at 1.17 V versus SCE in 0.5 M H$_2$SO$_4$ using the reflectance spectrum of pristine Ru at $-0.1$ V as a reference. Based on a comparison of the features observed with those of the genuine material (shown by the inset in the figure), the corrosion product could be identified as RuO$_4$.

![Figure 25](image)

**Figure 25** Background-corrected differential reflectance spectra for an Ru electrode in 0.5 M H$_2$SO$_4$. (- - -) Result obtained following a potential step from $-0.1$ to $+1.17$ V versus SCE. The inset shows the molar extinction coefficient $\varepsilon$ versus $\lambda$ for RuO$_4$. $^{(66)}$

4.4.1.2 Chronoabsorptometry

**Glancing Incidence – Systems Involving a Single Absorbing Product**

Some of the advantages associated with external reflection compared to transmission through an OTE may be illustrated using potential step chronoabsorptometry (see section 4.1) as an example. Assuming that the only optically absorbing species at the wavelength selected for the measurements ($\lambda$) is the product P of the electrochemical reaction, and that the heterogeneous electron transfer process is under strict diffusion control, $A(t)$ is given by Equation (63) corrected for the difference in optical path, i.e. $\eta = 2 / \cos \phi$, namely

$$A(t) = \varepsilon_P C_P \frac{2}{\cos \phi} \left( \frac{4D_R t}{\pi} \right)^{1/2}$$

Equation (66) has been verified in a number of laboratories for simple electrochemical processes. In particular, Figure 26(a) $^{(62)}$ shows absorbance versus time and Figure 26(b) the corresponding absorbance versus $t^{1/2}$ plots calculated from these data for a buffered solution (pH = 7) of 0.59 mM MV$^{+}$+. The potential in this case was stepped from $-0.3$ to $-0.8$ V versus SCE using an Au electrode with an He–Ne laser beam ($\lambda = 632.8$ nm) incident on the sample at $\phi = 88.52$°. At this energy MV$^{+}$+ displays significant absorption. The straight line in the figure was calculated based on values of $\varepsilon_P$ and $D_R$ reported in the literature (see Table 4). It is evident from these results that the agreement between theory and experiment is excellent for times longer than 10 ms. The discrepancies found at
shorter times were attributed to a variety of factors, a thorough discussion of which may be found in the original literature. Good quantitative agreement (<2%) was also observed between the theoretical and experimental values of η for φ in the range 88–89°, which corresponds to η values of about 50–100, for electrolysis times of the order of 50 ms. However, deviations were detected at shorter times and smaller φ. This technique has been successfully extended to the entire UV/VIS range by using a continuum light source and a well-collimated beam, augmenting significantly its overall versatility.

Glancing Incidence – Systems Involving an Absorbing Reactant and an Absorbing Product. In the case of systems in which both R and P in Equation (57) absorb at the same wavelength λ, Equation (66) must be modified to Equation (67):

$$A(t) = \Delta \varepsilon(\lambda)C_R^0 \frac{2}{\cos \phi} \left( \frac{4D_R}{\pi} \right)^{1/2}$$

where $\Delta \varepsilon(\lambda) = \varepsilon_P(\lambda) - \varepsilon_R(\lambda)$. Assume that after a certain period of time τ, following application of the step, the electrode potential is stepped to a new value at which the reverse reaction occurs under diffusion control. Equation (68) presents this in mathematical terms (see section 2.2.1),

$$C_R(0, t) = S_1 \text{ where } S_1 = \begin{cases} 0, & t \leq \tau \\ 1, & t > \tau \end{cases}, \dot{\theta}_R(0, t) = 1 - S_1,$$

and, hence,

$$Q(s) = \left( \frac{D_R}{s} \right)^{1/2} \theta_R(0, s) = \frac{D_R^{1/2}}{s^{3/2}} - D_R^{1/2} \frac{e^{s\tau}}{s^{3/2}} \quad (69)$$

After inversion of Equation (69) and substitution in Equation (25) the transient absorbance is given by Equation (70):

$$A(t) = \Delta \varepsilon(\lambda)C_R^0 \frac{2}{\cos \phi} \left( \frac{4D_R}{\pi} \right)^{1/2} \times \frac{1}{s^{1/2}} - S_1(\tau - t)^{1/2}$$

which reduces to Equation (54) for $t \leq \tau$, and, for the second step only Equation (71) holds:

$$A(t > \tau) = A(\tau) - \Delta \varepsilon(\lambda)C_R^0 \frac{2}{\cos \phi} \left( \frac{4D_R}{\pi} \right)^{1/2} \times \tau^{1/2} - t^{1/2} + (\tau - t)^{1/2}$$

An interesting application of this formalism was described by Jones and Hinman, who examined the redox properties of iron tetraphenylporphyrin chloride (FeTPPCl) in a nonaqueous solution, using the cell shown in Figure 24(a). Figure 27 shows a plot of ΔA versus t obtained for a 10.6µM FeTPPCl solution in 0.1 M tetra-n-butyl ammonium perchlorate (TBAP) in CH2Cl2 for an experiment in which the potential was stepped from 0.9 V to 1.3 V versus SCE for 1 min, and then stepped back to 0.9 V. A clear indication that the system behaves in an ideal way was obtained from the linear character of the plots of ΔA versus $t^{1/2}$, and ΔA versus $t^{1/2} - t^{1/2}$ + $(\tau - t)^{1/2}$ (Figure 28), which may be used as a criterion to ascertain that, within the timescale of the measurements, the product of the reaction P is stable. As the spectrum of R is often known, measurements of this type at different values of λ, allow the spectrum of the other species to be determined, yielding in this case
Figure 27 Plot of $\Delta A$ versus $t$ obtained at $\lambda = 410$ nm in a 10 $\mu$M FeTPPCl solution in CH$_2$Cl$_2$ containing 0.1 M TBAP during a double potential step chronoabsorptometric experiment. The data represent an average of 64 measurements.\(^{64}\)

Figure 28 Plots of (a) $\Delta A$ versus $t^{1/2}$ and (b) $\Delta A$ versus $\varphi = t^{1/2} - t^{1/2} + (\tau - a)^{1/2}$ obtained from the data in Figure 27. The broken lines represent a linear least-squares fit.\(^{64}\)

Figure 29 UV/VIS spectrum of FeTPPCl (-----) and its one-electron oxidation product (○) calculated from chronoabsorptometric data.\(^{64}\)

Excellent agreement with that of the oxidized form of FeTPPCl obtained by other means (Figure 29).

**Multiple Reflection.** A different approach\(^{(39)}\) to increasing the pathlength is to introduce a well-collimated beam into a cell consisting of two working electrodes placed parallel, and at close distance from each other, as shown schematically in Figure 24. Under these conditions and assuming P is the only absorbing species, $A(t)$ for this multiple reflection configuration is given to a good degree of approximation by

$$A(t) = \frac{\varepsilon P C_P^0}{T \sin \phi} \frac{2w}{T \sin \phi} \left( \frac{4D_P t}{L} \right)^{1/2}$$

where $w$ and $T$ are the cell length and cell thickness, respectively. According to Equation (72) the further enhancement in absorbance derived from multiple, compared to single, reflection amounts to a factor $L/(T \tan \phi)$. For systems in which the only absorbing species at $\lambda$ is the reactant R, the decrease in absorbance after a potential step will also be linear in $t^{1/2}$, namely,

$$A(t) = \frac{\varepsilon R C_R^0}{\sin \phi} \frac{L}{T \sin \phi} \frac{2L}{T \sin \phi} \frac{4D_R t}{L} \left( \frac{4D_R t}{L} \right)^{1/2}$$

The leading term in Equation (73) represents the initial absorbance of the solution, a factor which is independent of $T$, and $L/\sin \phi$ represents the total pathlength.

Shown in Figure 30 are $A$ versus $t^{1/2}$ plots for the reduction of MB on Au in 0.1 M KCl solutions buffered (pH = 7) obtained with the cell shown in Figure 24(c), using an He–Ne laser, following a potential step as a function of MB concentration. Excellent linearity was observed within the timescale of the measurements, except for the most concentrated solution, for which the electrogenerated radical undergoes precipitation.
Furthermore, the magnitude of $A$, based on $e$ for MB at 632.8 nm (see Table 4), the geometry of the cell and the angle of incidence, was in agreement with that found experimentally with $\phi < 45^\circ$ for about 330 reflections.

4.4.1.3 Determination of Rate Constants of Homogeneous Electron Transfer Reactions Involving Electrogenerated Species

Consider a reaction involving exclusively solution-phase species, $A$, $A^{+*}$, $B$ and $B^0$, in which $A$ is reduced at the electrode surface to yield $A^{+*}$, which then reacts with $B$ to yield $B^0$ regenerating $A$ (Equation 74):

$$2A^{+*} + B \rightarrow 2A + B^0$$  \hspace{1cm} (74)

Two simple reaction mechanisms consistent with this stoichiometry may be envisaged as Equation (75) with (76), and Equation (75) with (77):

$$A^{+*} + B \xrightarrow{k_2} B^{+*} + A$$  \hspace{1cm} (75)

$$A^{+*} + B^{+*} \xrightarrow{\text{fast}} B^0 + A$$  \hspace{1cm} (76)

$$2B^{+*} \xrightarrow{\text{fast}} B + B^0$$  \hspace{1cm} (77)

Assume further, that the rate-determining step is first order both in $A^{+*}$ and $B$, such as a collision between these species, and that the equilibrium constant for the overall reaction is large so that all reactions following the slow step will proceed to completion. Hence, if Equation (75) is slower than (76) and (77), then Equation (78) holds:

$$\frac{d[A^{+*}]}{dt} = -2k_2[A^{+*}][B]$$  \hspace{1cm} (78)

If an electrode immersed in a homogeneous solution containing $A$ and $B$ at known concentrations is stepped to a potential sufficiently positive to form the corresponding radical cation $A^{+*}$ under strict diffusion control diffusing into the solution, then $A^{+*}$ will encounter and react with $B$ diffusing toward the electrode in an electron transfer-type process to yield $B^{+*}$. As the amount of $B$ at, and near the surface is expected to be small, Equation (75) will proceed a distance away from the electrode. Analytic solutions of this rather complex problem do not exist in general; however, it is possible to generate concentration profiles of each of the species involved by digital simulation techniques, provided that all the relevant parameters are specified and, from these, to predict the absorbance associated with the chromophores.

The power of UV/VIS spectroelectrochemistry as a tool to determine rate constants of reactions between an electrogenerated radical with a species in solution, i.e. $k_2$ in Equations (76) and (77), was demonstrated by McCreery et al.,\cite{67} who measured the rates of CPZ$^{+*}$ with a catecholamine, using, among other techniques, grazing incidence external reflection at a Pt electrode.

Figure 31 shows the results of numerical simulations for the reaction sequence shown above, as $C_{CPZ^{+*}}$ observed in the presence and in the absence of catecholamine, denoted as DA, as a function of distance, expressed in terms of units of $(Dt)^{1/2}$, for four different values of $kt$ assuming equal bulk concentrations for both CPZ and DA. For simplicity, the diffusion coefficients of all species involved were assumed to be the same. Figure 31(a) corresponds to a situation in which $k_2 = 0$, i.e. no subsequent reaction involving CPZ$^{+*}$. For $k_2$ finite and $t \neq 0$, the concentrations of both $C_{CPZ^{+*}}$ and $C_{DA}$ at a fixed distance from the electrode decrease, and therefore the extent of overlap between the two profiles of the two species, also diminishes.

Based on arguments set forward in previous sections, the absorbance of a chromophore is proportional to the integral of the concentration profile, enabling comparisons to be made with experimental measurements. Figure 32 shows normalized absorbances, i.e. those obtained in the presence and in the absence of equimolar amounts of DA, monitored at wavelengths at which only DOQ, the oxidation product of DA ($\lambda = 400$ nm, upper curve), and CPZ$^{+*}$ ($\lambda = 525$ nm, all

Figure 31 Simulated concentration versus distance profiles for the EE/C reaction sequence at various values of $\beta$ and $kt$: (a) $C_{CPZ} = C_{DA}$ ($\beta = 1$); (b) $C_{CPZ} = 2C_{DA}$ ($\beta = 2$). In all cases the ordinate represents fractional concentration relative to the $C_{CPZ}$ value. DOQ, dopamine quinone.

other curves) absorb, respectively. Also included in these plots as solid lines are best-fit numerical simulations for $\beta = C_{CPZ}/C_{DA}$, of 0.5, 1, 2, and 5.5, yielding $k_2$ values of $2.12 \pm 0.25 \text{ M}^{-1} \text{s}^{-1}$.

4.4.2 Microelectrodes
Planar electrodes of dimensions larger than about 0.1 mm suffer from relatively slow diffusional relaxation; hence, long times are required to recover the initial conditions
Figure 32 Normalized absorbance versus $\log(kC^\beta t)$ for various values of $\beta$. The solid curves are theoretical plots for DOQ monitored at $\lambda = 400$ nm (top curve) or CPZ monitored at $\lambda = 525$ nm (remaining curves). Points are best fits to experimental data.\(^{(23)}\)

and, thus, acquire sufficient measurements over reasonable times for efficient signal averaging. Considerable enhancements in mass transport in quiescent solutions can be realized by using electrodes of micrometer dimensions, including disks and cylinders. Despite their size, the absorbance observed for such microelectrodes in the external reflection mode is larger than that using an OTE for similar electrolysis times. Because of their small area, both capacitive and faradaic currents are small, placing lower demands on the potentiostat power, increased time averaging, higher duty cycle, low cell-time constants, more precise solution resistance and, most importantly, better conditions for studies of fast reactions.

4.4.2.1 Microcylinders An analytic expression for the time-dependent concentration profile of a species P in a stagnant solution, produced at the circumference of a circular electrode of radius $r_0$, via oxidation or reduction of R under chronocoulometric conditions, can be obtained by solving the appropriate Fick’s law using the Laplace transform method. The solution to this problem may be shown to be given by Equation (79).\(^{(37)}\)

$$C_P(r, t) = C_R^0 \left[ 1 + \frac{2}{\pi} \int_0^\infty \frac{J_0 \left( \frac{r}{r_0} \xi \right) Y_0(\xi) - Y_0 \left( \frac{r}{r_0} \xi \right) J_0(\xi)}{J_0^2(\xi) + Y_0^2(\xi)} \exp\left( -\frac{D_R t r_0^2 k^2}{\xi} \right) d\xi \right]$$

where $J_0(\xi)$ and $Y_0(\xi)$ are Bessel functions of order zero of the first and second kind of argument $\xi$, respectively.\(^{(23)}\)

Figure 33 shows a plot of $A_{cyl}/A_{pl}$ where $A_{cyl}$ and $A_{pl}$ represent the absorbances observed with a cylinder by integration of Equation (79) along $r$, and with a planar electrode (see Equation 64), respectively, as a function of the dimensionless variable $(D_R t)^{1/2}/r_0$. As would be expected, $A_{cyl}/A_{pl}$ is close to unity for $\delta_N < r_0$ (see Figure 33), but deviates significantly at longer times for fixed $r_0$.

Figure 34 shows average absorbance versus $t^{1/2}$ plots in the range 0.1–100 ms following a potential step from 0.3 to 1.1 V versus SCE in solutions of 3.5 mM OD in 1 M H$_2$SO$_4$ using a Pt microcylinder with $r_0 = 12.5$ µm. The open circles in this figure were obtained based on the theory introduced above without adjustable parameters. Similar data over a much shorter timescale, down to 4 µs, could be recorded using a Pt microcylinder with $r_0 = 5$ µm in 2.2 mM OD in 1 M H$_2$SO$_4$ after 2700 averages, under otherwise identical conditions. In this latter case, deviations of only up to 5% could be observed at 1 ms. Both of these experiments involved the use of a laser focused onto the cylinder wall as the radiation source, and optical fibers to collect the reflected light in a two-electrode configuration (Figure 35). The primary factor that limits a quantitative analysis of data acquired at longer times relates to thermal effects induced by heat dissipation within the electrode. Such phenomena restrict the range of validity of the model to times at which $\delta_N$ is less than twice the electrode radius, i.e.
Figure 34 Absorbance versus \( t^{1/2} \) for a 12.5 µm radius platinum electrode in 1 M H₂SO₄ containing 3.5 mM OD (o-dianisidine): open circles = theoretically predicted response; solid line = experimental response for a conventional three-electrode arrangement, average of 100 runs; solid circles = response for a two-electrode configuration, average of 60 runs. \( E_{\text{app}} \) was stepped from 0.3 to 1.1 V versus SCE.\(^{(37)}\)

Figure 35 Experimental arrangement for UV/VIS spectroelectrochemical measurements involving a microcylinder electrode.\(^{(37)}\)

\((Dt)^{1/2}/r_0 < 2\). As discussed by these authors, both the IR drop, and the time constant of the cell increase as \( r_0 \) decreases; hence, smaller-diameter electrodes will not allow access to measurements for times shorter than a few microseconds. Nevertheless, it is possible to achieve submicrosecond resolution by employing a microdisk electrode, as described in the next subsection.

4.4.2.2 Microdisk Electrodes Unlike the case of cylindrical electrodes, the solution resistance \( R_{\text{sol}} \) for a microdisk is directly, as opposed to inversely, proportional to \( r_0 \). As for a typical microdisk electrode, the contribution of the capacity to \( \tau_{\text{cell}} \) is very small compared to that ascribed to \( R_{\text{sol}} \); decreasing \( r_0 \) should lead to a better transient response. Indeed, chronoabsorptometric experiments involving the use of a coaxial Au microdisk electrode with \( r_0 = 30 \mu m \) in a two-electrode cell configuration, allowed for absorbances associated with electrogenerated MV\(^{2+} \) to be monitored in the millimeter range with an Xe arc lamp down to 150 ns following extensive signal averaging (Figure 36).\(^{(31)}\) This improved methodology enables measurements of second-order homogeneous rate constants of reactions involving electrochemically generated strong chromophores (\( k_2 \) in Equation 75), of the order of \( 10^5 \text{ M}^{-1}\text{s}^{-1} \), as illustrated by the reaction of CPZ with DA at physiological pH. It should be emphasized that these values exceed those achievable with more conventional stopped flow experiments.

Shown in Figure 37 are absorbance versus time plots for generation of CPZ\(^{2+} \) both in the absence and in the presence of DA. The solid lines in the lower curve represent best digital simulation fits to the average of 1120 runs, for which \( k_2 \) for the reduction of the radical

Figure 36 Absorbance versus time curves for the generation of MV\(^{2+} \) from 5.6 mM MVCl₂ in 2 M phosphate buffer, (pH = 7.0) recorded using a coaxial Au microdisk working electrode (30 µm radius) with an He–Ne laser at \( \lambda = 632.8 \text{nm} \). The dashed line is an average of 60000 runs covering 1–200 µs. The solid noisy line is a shorter transient at higher time resolution. The straight line is a least squares fit to all of the data, and has the same slope as 5 ms runs.\(^{(31)}\)
Figure 37 Absorbance versus time curves for the generation of CPZ$^{+}$ in the presence (lower curve) and absence (upper curve) of equimolar DA in 40% MeOH/H$_2$O, containing 0.2 M dimethylarsenate buffer (pH = 6.8) plus KCl for a total ionic strength of 1.8 M. The noisy lines are averages of 1120 runs. The upper smooth curve was calculated for $k = 0$, the lower curve for $k = 6.2 \times 10^7$ M$^{-1}$ s$^{-1}$ for the reduction of the radical by dopamine.$^{(31)}$

by DA is $6.2 \times 10^7$ M$^{-1}$ s$^{-1}$ (lower curve), whereas that in the upper curves assumes $k_2 = 0$.

4.5 Spatially Resolved Spectroelectrochemistry

Transmission and external reflection spectroelectrochemical methods afford information about integrated profiles of the species being monitored. Additional insight into mechanistic aspects of homogeneous-phase redox reactions and transport phenomena can be obtained from the concentration profiles themselves. Not surprisingly, considerable effort has been devoted to monitor their temporal and spatial evolution using both interferometry$^{(14)}$ and transmission spectroscopy. This section summarizes the most salient features of the latter of these two methodologies and discusses with various illustrations its scope of applicability.

The problems associated with the lack of selectivity and rather weak sensitivity of solution-phase imaging techniques based on interferometry so far reported can be circumvented to a significant extent by using absorption, as opposed to refraction, as the physical phenomenon being monitored. Although restricted to systems involving one or more chromophores, absorption-imaging methods have provided a wealth of high spatial resolution information regarding the time evolution of diffusion profiles induced by heterogeneous electron transfer reactions at electrode–solution interfaces approaching the limits imposed by optical diffraction. Because of the rather low concentrations of reactants often involved in spectroelectrochemical experiments, distortions in the spatially resolved profiles measured by absorption, induced by changes in the index of refraction, can be neglected.

Two types of absorption-based profile imaging methods$^{(40,69)}$ have been described in the literature, involving in both cases weakly focused light propagating parallel to the electrode surface. The first, depicted in Figure 38(a),$^{(68)}$ employs a moving mechanical slit aligned along an axis normal to the electrode, and a photomultiplier to measure the extent of light attenuation through small volumes of solution. The second approach$^{(40,69)}$ (Figure 38b), relies on a photodiode array detector to capture the magnified image of the beam produced either by a laser or a lamp, after crossing the diffusion boundary layer, as a function of time. Analysis of the projection of an expanded image onto such an array enables, within diffraction-limited resolution, construction of time-resolved and spatially resolved maps of light intensities, which can then be related to a physical variable of the system being examined, such as concentration, as a function of distance normal to the probing beam.
4.5.1 Imaging of Diffusion Layers

4.5.1.1 Potential Step

Planar Electrodes. Figure 39 shows a series of $C_{TAA^*}/C_{TAA}$ versus $y$ (the distance from the electrode surface) plots obtained for single and double potential step experiments in 2.56 and 4.06 mM TAA in acetonitrile solutions, respectively. As shown in Table 4, the species TAA$^{**}$ exhibits a large $\varepsilon$ at $\lambda = 632.8$ nm. Each of the solid curves in (a) and (b) were acquired with an He–Ne laser at different times after application of a potential step from 0.0 to +0.8 V versus SCE, whereas those in (c) and (d) were recorded at various times after returning the potential to 0 V, following polarization at +0.8 for 2 s (see caption). Excellent agreement was found between the results of these experiments using values of $\varepsilon$ and $D$ obtained independently, based on solutions of Fick's law (see Equation 23). Deviations observed at times longer than 8 s in (a) and (b), are attributed to the onset of natural convection.

Microelectrodes. Imaging techniques have also been implemented for the analysis of cylindrical diffusion fields around thin wires. In this case, a parallel beam of light of dimensions larger than the diameter of the wire is directed normal to the cylinder axis, as

Modifications to the optical set-up in Figure 40, to include an Xe arc lamp instead of a laser, makes it possible to gain access to a much wider spectral region and thereby monitor profiles of a more general class of chromophores. Using such an approach, direct verification of theoretical predictions for times up to 10 s could be obtained for the potential step oxidation of ferrocyanide ion $[Fe(CN)_{6}]^{4-}$ to the corresponding ferric species.

Overall, analysis of these type of data allows for $D$ for both R and P to be determined without specific knowledge of electrode areas, concentration, molar absorptivity, absorbance, number of electrons transferred or current, as would be required by chronoamperometry and chronooabsorptometry.
shown in Figure 41, and then magnified before striking the array detector. Concentration profiles based on information obtained from lateral absorbances can be obtained by a mathematical technique known as Abel inversion, a procedure readily amenable to computer implementation. Experimental results in agreement with theoretical predictions have been obtained for microwires of radii 6–25 µm and electrolysis times ranging from 50 ms to several seconds. Good agreement between theory and experiments were obtained for $C(r)$ for various times following the potential step, as shown in Figure 42.

4.5.1.2 Cyclic Voltammetry  The same experimental approach enables images of concentration profiles to be obtained for planar electrodes during cyclic voltammetry.\(^{(40)}\) For example, Figure 43(a) shows profiles recorded during the forward and Figure 43(b) reverse sweeps for the TAA/TAA\(^{+}\) redox system in acetonitrile. Also depicted in the insert to Figure 43(a) is a plot of absorbance versus potential obtained with a photomultiplier tube (PMT), instead of a diode array, through a slit (see Figure 38) illuminating the region 0.0 ± 0.2 µm, i.e. very close to the electrode surface, under the same conditions. For scan rates up to ca. 80 mV s\(^{-1}\), these curves displayed virtually no hysteresis. At the half-wave potential, i.e. $E_{1/2} = 0.54$ V versus SCE, the surface concentrations of TAA and TAA\(^{+}\) are equal. Under these conditions, the surface absorbance should then be half that of the maximum absorbance for full TAA oxidation, which can be measured at the most positive potentials (see Figure 43). Furthermore, the overall magnitude and shapes of these curves are consistent with the predicted Nernstian behavior for fast heterogeneous electron transfer.

Although the concentration profiles of TAA\(^{+}\) recorded during the forward and reverse scans show common values for the surface concentration, large differences are observed away from the electrode (see Figure 43). This is not surprising as TAA\(^{+}\) accumulates
**ULTRAVIOLET/VISIBLE SPECTROELECTROCHEMISTRY**

Figure 43 (a) Absorbance versus \( y \), for the forward scan. (b) Same as (a) for the reverse scan during a cyclic voltammogram recorded at a scan rate of 80 mV s\(^{-1}\) in solution, \( C_{\text{TAA}} = 3.6 \text{mM} \) (see text for details). The inset shows the potentials at which the diode array was triggered to obtain the absorbance profiles.

4.5.2 Imaging of Reaction Layers

The ability of measuring time- and space-resolved profiles can be advantageous for the evaluation of rate constants of homogeneous electron transfer reactions involving electrogenerated species and the diagnosis of reaction mechanisms.

4.5.2.1 Determination of Rate Constants

Scheme 9 represents a process in which a species \( S \), produced by the oxidation of \( R \), reacts with another electroactive species \( P \) to regenerate \( R \) and the oxidized form of \( P \), denoted as \( Q \). The equilibrium constant of the overall reaction is given by Equation (80):

\[
\frac{[R]^n_1[O]^{n_2}_1}{[S]^{n_1}[P]^{n_2}} = K_{\text{eq}}
\]  

During the forward scan, diffusing away from the electrode.

The magnitude of \( K_{\text{eq}} \) can be calculated directly from the values of the formal reduction potentials of the two redox couples involved. As demonstrated by theoretical calculations, the concentration profiles of these species are very sensitive to the reaction parameters, including stoichiometry (i.e. \( n_2/n_1 \)), \( C_P/C_R \), \( K_{\text{eq}} \) and the rate constant, often expressed in terms of a dimensionless quantity \( \gamma = k_1 C_R^0 t \).

An example of this type of mechanism\(^{41,72}\) is provided by the oxidation of methoxypromazine (MPZ) by the electrochemically generated CPZ\(^{**} \) (\( = \)S) at potentials at which MPZ\(^{**} \) (\( = \)Q) is also produced as shown in Scheme 10. Equation (81) gives the equilibrium constant for the overall reaction:

\[
K_{\text{eq}} = \frac{k_1}{k_{-1}} = \exp \left( \frac{nF}{RT} (E_1 - E_2) \right) = 159
\]  

For these studies, the He–Ne laser was replaced by an Xe arc lamp, thereby allowing the beam to be tuned to the specific absorption bands of the chromophores, i.e. CPZ\(^{**} \) and MPZ\(^{**} \). The contributions due to MPZ\(^{**} \) to the absorbance at \( \lambda = 520 \text{nm} \), the absorption maxima of CPZ\(^{**} \), can be determined from the results obtained at 600 nm, a wavelength at which CPZ\(^{**} \), CPZ, and MPZ do not absorb. A comparison between experimental results (solid lines) and best fit simulations (dotted lines) in the form of \( C(y, t)/C_{\text{CPZ}}^0 \) versus \( y \), where \( y \) is the distance normal from the electrode surface, for \( \lambda = 600 \text{ nm} \) and 520 nm, are given in Figure 44(a) and (b), respectively, for \( t = 1, 3 \) and \( 6 \text{ s} \), assuming \( K_{\text{eq}} = 159, n_1 = n_2, \gamma = k_1 C_R^0 t = \infty \). The latter condition simply implies that the reaction rate is very large, i.e. no kinetic information can be inferred from this analysis.

Equally large rate constants were found for the cross-reaction between triflupromazine hydrochloride (TPZ) and hydroquinone (H\(_2\)Q) for which \( n_2/n_1 = 2 \). As for \( K_{\text{eq}} \), absolute values of \( n_1 \) and \( n_2 \), can be obtained using conventional electrochemical techniques, or spatially resolved spectroelectrochemistry for the individual redox couples.
ELECTROANALYTICAL METHODS

Figure 44 (a) Experimental (---) and simulated (···) concentration profiles for the CPZ**/MPZ cross-reaction: curves A–C are CPZ**, curves a–c are MPZ**. Simulations are for $k_1$, $g_D$, $K_{eq} = 159$. Curves: (A, a) $t = 2$ s; (B, b) $t = 3$ s; (C, c) $t = 6$ s. Experimental profiles determined at $\lambda = 600$ nm for MPZ**, and at $\lambda = 520$ nm for CPZ**, corrected for absorption due to MPZ**. (b) Experimental (---) and simulated (···) absorbance profiles determined at $\lambda = 520$ nm for the CPZ/CPZ** cross-reaction. $g$, $k_1 = \infty$, $K_{eq} = 159$. Curves: (a) 1 s; (b) 3 s; (c) 6 s.

Careful inspection of simulated profiles for the reaction mechanism in Scheme 10 reveals for large values of $K_{eq}$ and infinitely large values of $g$, a rather linear region extending from the electrode, at which the dimensionless concentration of S under the operating diffusion control conditions is unity, into the solution. Extrapolation of this profile onto the abscissa may be used to define a dimensionless reaction layer thickness, denoted $d_r$, a parameter that depends on $n_2/n_1$, and the relative bulk concentrations of P and R.

4.5.2.2 Mechanistic Diagnosis

Methods based on the measurement of integrated profiles by absorption techniques yielded data consistent with at least two proposed mechanisms for the oxidation of DA by CPZ**, already given in Equations (75–77). In other words, it was not possible to discern whether DA** reacts with CPZ** or undergoes dismutation (see Equations 76 and 77) to yield the specified products. As evidenced by numerical simulations, however, the spatial and temporal profiles of CPZ** do indeed show differences for these two mechanisms and, therefore, direct observation could help identify the preferred pathway.

Comparisons between experimental and theoretical data provided unambiguous proof that Equation (75) with (77) is not operative, thus favoring stepwise electron transfer (Equations 75 and 76) as being the most likely mechanism. Moreover, analysis of the data obtained with a wire electrode revealed that under very acidic conditions the reaction between the neutral species CPZ and DOQ cannot be neglected, i.e. the rate constant is indeed significant. Overall, there appears to be no other method available to date capable of providing this level of detail regarding such a complex reaction.

4.6 Ultraviolet/Visible Spectroelectrochemistry in the Presence of Convective Flow

The specificity of spectroscopic techniques, together with the well-defined mass transport characteristics of the rotating disk electrode (RDE), the rotating ring-disk electrode (RRDE), the channel electrode and, to a lesser extent tube electrodes, provide excellent experimental tools for the quantitative analysis of complex electrode processes. This section illustrates with representative examples, theoretical and experimental aspects of the coupling of UV/VIS spectroscopy and forced convection systems, both under steady-state and transient conditions.

4.6.1 Steady-state Measurements

4.6.1.1 Near Normal Incidence Ultraviolet/Visible Reflection–Absorption Spectroscopy at Rotating Disk Electrodes

Optical access to the diffusion boundary layer of an RDE under near-normal incidence conditions requires an experimental arrangement of the type depicted in Figure 45. The beam enters through a window parallel to the electrode surface, travels along the axis of rotation of the disk, reflects off the electrode surface and, after emerging from the cell through the same window, is directed toward the detector. Care must be exercised to set the distance between the electrode surface and the window (Figure 45) sufficiently long to preserve the laminar fluid flow characteristics undisturbed. The amount of product generated during the experiments will be assumed to be sufficiently small so that the bulk solution composition remains unaltered during data acquisition. Such requirements will be closely fulfilled provided the currents are small, the experiments short and the volume of the solutions large. For small incidence angles, such as those used in practice, the
errors introduced by assuming strict normal incidence are relatively small and therefore will be neglected.

**Simple Redox Reactions.** Steady-state concentration profiles for a stable product P generated at a RDE along the rotation axis of the disk can be obtained by solving Equation (33) in Table 2, assuming variations in the radial coordinate can be ignored, to yield Equation (82):

$$C_P(\zeta) = \frac{C_P^*}{\Gamma(4/3)} \exp(-u^3) \, du$$

On this basis, the absorbance due to P is given by Equation (83):

$$A(E) = 1.62936 e^{1/6} D_R^{2/3} D_P^{-1/3} \omega^{-1/2} \left(1 - \frac{C_P^*(E)}{C_R^*}\right) \exp(-u^3) \, du$$

At the diffusion-limited current as a function of $\omega^{-1/2}$ was found to be linear, yielding values for $\varepsilon$ of $[\text{Fe(CN)}_6]^{3-}$ within about 1% of those reported in the literature.

**Determination of Faradaic Efficiencies of Complex Processes.** Electrosynthesis affords an expedient route for the industrial production of a variety of high-valued chemicals. In addition to cell design considerations and electrode stability, the overall efficiency of these processes is often controlled by the kinetics of heterogeneous electron transfer, as well as by the rates of preceding and subsequent chemical reactions. Of common occurrence are situations in which materials, other than the desired product, are generated during operation, thereby decreasing the specific faradaic efficiencies, i.e. the fraction of the total current (or charge) involved in the generation of a given product. Quantitative aspects of this phenomenon may be assessed by determining product distributions using conventional analytical techniques external to the reactor or cell. A far more desirable strategy is to acquire such information in situ or on line, i.e. by probing directly the solution adjacent to the electrode surface under well-defined conditions of mass transfer, especially when dealing with rather unstable products.

Within the Levich formalism, the flux $j_P$ of a non-adsorbing product P at the surface of a RDE, may be expressed in terms of the partial current density due to the formation of P (Equation 84):

$$D_P \left(\frac{dC_P}{dy}\right)_0 = \frac{-j_P}{n_P F}$$

where $n_P$ is the number of electrons required to form one molecule of P. This parameter is defined as negative or
positive depending on whether the process is a reduction or an oxidation, respectively. As is customary, the sign of the current is positive for an oxidation and negative for a reduction.

In terms of the dimensionless variable \( C_p = y/\delta_p \), where \( \delta_p = 1.805 D_p^{1/3} \nu^{1/6} \omega^{-1/2} \) is the thickness of the diffusion boundary layer for \( P \), Equation (84) can be rewritten as Equation (85):

\[
\left( \frac{dC_p}{dC_p} \right) = \frac{-j_p \delta_p}{n_p F D_p} \quad (85)
\]

The solution for the profile of a stable product \( P \), i.e. displaying no decomposition, along an axis normal to the electrode surface at steady state may be expressed in terms of the flux at the surface (Equation 86):

\[
C_p(\xi_p) = - \int_0^\infty \frac{-j_p \delta_p}{n_p F D_p} \exp(-u^3) \, du \quad (86)
\]

For normal incidence reflection absorption experiments at an RDE, and assuming \( P \) is the only optically absorbing species in the media, the absorbance \( A \) is given by

\[
A = 2\epsilon_p \int_0^\infty C_p(\xi_p) \, d\xi_p = 2\epsilon_p \int_0^\infty C_p(\xi_p) \, d\xi_p
\]

\[
= 2\epsilon_p \frac{\delta_p^2}{D_p} \frac{j_p}{n_p F} \int_0^\infty \exp(-u^3) \, du \, d\xi_p \quad (87)
\]

The value of the double integral in the right-hand side of Equation (87) is \( \Gamma(2/3)/3 \), where \( \Gamma(2/3) \) is the gamma function of argument \( 2/3 \). Hence, upon rearrangement, Equation (87) may be written as

\[
A = \frac{\omega}{2.9408} \epsilon_p \frac{\sqrt{v}}{D_p} \quad (88)
\]

As the right-hand side of Equation (88) involves parameters intrinsic either to the product \( (\epsilon_p, n_p, D_p) \) or to the solution \( (\nu) \), the quantity \( A \omega/\nu \) is constant. In fact, the constancy of this ratio for different \( E \), \( \omega \), and \( C_R \) may be regarded as proof that the process indeed satisfies the requirements of the model. Note that in the derivation of Equation (88), no restrictions were imposed on the nature of the step-limiting the values of \( j_p \), such as diffusion, heterogeneous or homogeneous reactions, or a combination thereof.

The reduction of bisulfite in mildly acidic solutions generates dithionite \( S_2O_4^{2-} \), a material that displays a high \( \epsilon \) band centered at \( \lambda = 316 \) nm, i.e. within a spectral region that does not interfere with other species in the media.

**Figure 47** Current density \( j \) (solid line), partial current density for dithionite generation \( j_p \) (points), and difference between these two currents \( j_{res} \) (dotted line), obtained with an Au disk (area 0.452 cm\(^2\)) of an Au–Au RRDE assembly in 10 mM Na\(_2\)SO\(_3\) in 0.50 M phosphate buffer solution (pH = 5.25), at different rotation rates: \( \lambda = 200 \), \( B = 400 \), \( C = 900 \), \( D = 1600 \), \( E = 2500 \), and \( F = 3600 \) rpm. Values of \( j_p \) were calculated from Equation (86) based on the absorbance measured in the reflection absorption mode at near-normal incidence at \( \lambda = 316 \) nm.

Plots of \( j \) versus \( E \), known as polarization curves, where \( j \) is the total current density, were recorded with an Au RDE in solutions of 10 mM Na\(_2\)SO\(_3\) in 0.50 M NaH\(_2\)PO\(_4\) adjusted to pH 5.25 with NaOH using the arrangement shown in Figure 45. At all rotation rates examined, the currents at the inflection (solid lines in Figure 47), were significantly smaller than the diffusion-limited current densities \( j_{lim} \) for the two-electron oxidation of sulfite in the same electrolyte at 1.00 V, e.g. \( j_{lim} = 19.1 \) mA cm\(^{-2}\) at 900 rpm.

Plots of \( A \) at 316 nm versus \( E \) recorded during acquisition of \( I \) versus \( E \) curves in Figure 47, were used to construct \( j_p \) versus \( E \) plots using Equation (86), and are given in scattered form in the same figure. For these calculations, the constant \( A \omega/\nu \) was determined based on \( \epsilon \) of \( S_2O_4^{2-} \), i.e. \( 7.3 \pm 0.3 \times 10^6 \) cm\(^2\) mol\(^{-1}\) cm\(^{-1}\), and the diffusion coefficient of \( S_2O_4^{2-} \), i.e. \( 9.1 \pm 0.03 \times 10^{-6} \) cm\(^2\) s\(^{-1}\), respectively, \( v = 0.010 \) cm\(^2\) s\(^{-1}\), the kinematic viscosity of water, and \( n = 2 \), yielding a value of \( 9.9 \pm 0.6 \) rpm cm\(^2\) mA\(^{-1}\). Also given in this figure are plots of \( j_{res} \) versus \( E \), where \( j_{res} \) is the contribution to the total current \( j \) due to processes other than bisulfite reduction to dithionite, \( j_{res} = j - j_p \).

In the range \(-0.60 > E > -0.75 \) V, \( j \) and \( j_p \) were found to virtually coincide at \( j_{res} \) about 0. This observation provides convincing evidence that \( j \) and \( j_p \) are not only proportional, but also that the specific faradaic efficiency \( (j_p/j) \) for dithionite generation under these conditions is
within experimental error about 100% (Figure 48). The decrease in the specific faradaic efficiency at more positive potentials is probably caused by contributions to the total current due to the reduction of adventitious oxygen in the solution. Furthermore, \( j_P \) increased with \( \omega \) over the entire potential range, indicating that the reaction proceeds under partial mass transport control. However, despite the increase in \( j \) as the potential was made more negative, \( j_P \) reached a maximum at about \(-0.80 \text{ V (} j_P^\text{max})\) for all \( \omega \), and decreased steadily thereafter. In addition, plots of \( j_P^\text{max} \) versus \( \omega^{1/2} \) and \( 1/j_P^\text{max} \) versus \( 1/\omega^{1/2} \) yielded straight lines with nonzero intercepts, and \( j_{\text{res}} \) was found to be independent of \( \omega \).

### 4.6.1.2 Rotating Disk Electrode with a Concentric Transparent Ring

An interesting forced convection system introduced by Debrodt and Heusler,\(^{75}\) involves a conventional RRDE assembly in which the metal ring is replaced by a material transparent in the UV/VIS region. This device makes it possible to detect optically absorbing species generated at the disk electrode (Figure 49). Although certain theoretical aspects of this RRDE electrode have been analyzed by digital simulation techniques,\(^{76}\) analytical solutions can be obtained for simple reactions via the unified formalism given in Tables 2 and 3.\(^{77}\) Specifically, the dimensionless concentration and flux of a reactant, or a product along the surface of an RDE are constant, and given by \( \Theta = \frac{\theta}{\theta^0} = 3 \left( \frac{\Gamma(1/3)}{\Gamma(2/3)} \right)^{-1} \exp \left\{ \frac{-\zeta^3}{(1-\rho/\rho')} \right\} \times \left[ 1 - \left( \frac{\rho}{\rho'} \right)^{3/2} \right] \rho' d\rho' \) (Equation 89),

expressed as Equation (89),

\[
\Theta = \frac{\theta}{\theta^0} = 3 \left( \frac{\Gamma(1/3)}{\Gamma(2/3)} \right)^{-1} \exp \left\{ \frac{-\zeta^3}{(1-\rho/\rho')} \right\} \times \left[ 1 - \left( \frac{\rho}{\rho'} \right)^{3/2} \right] \rho' d\rho' \tag{89}
\]

which at \( \zeta = 0 \) reduces to Equation (90):

\[
\Theta(\rho > 1, \zeta = 0) = \frac{3}{4} + \sqrt{\frac{3}{4}} \pi \ln \frac{1 + g^3}{(1 + g)^3} - \frac{3}{2} \pi \arctan \left[ \frac{(2g - 1)^{1/3}}{\sqrt{3}} \right] \tag{90}
\]

where \( g = (\rho^3 - 1)^{1/3} \). Concentration profiles along \( \zeta \) for three values of \( \rho \) are given in Figure 50.

The integrated profile along \( \zeta \), defined as \( I(\rho) \) may be written as Equation (91):

\[
I(\rho) = \int_0^\infty \Theta(\rho, \zeta) d\zeta = \frac{\Gamma(1/3)}{\Gamma(2/3)} \left( \frac{\rho'}{\rho^3 - \rho^3} \right)^{-2/3} \left\{ 1 - \left( \frac{\rho}{\rho'} \right)^{1/3} \right\} d\zeta d\rho' \tag{91}
\]

A plot of \( I(\rho) \) versus \( \rho \) is shown in Figure 51(a).

An explicit expression for the total amount of material probed by the light beam, defined by a cylindrical shell...
Figure 50 Plot of \( \theta(\rho, \zeta) \) versus \( \zeta \) for three values of \( \rho \), i.e. curve 
a = 1, b = 65.5/64.5, and c = 74.5/64.5.\(^{(77)} \)

Equation (92):

\[
N_{\text{vol}} = N_0 \delta^D \left\{ \int_{\rho_1}^{\rho_2} I(\rho; \beta) \rho \, d\rho \right\}
= N_0 \delta^D [A(\rho_2) - A(\rho_1)]
\]  

where \( A(\rho) \) is given by Equation (93),

\[
A(\rho) = 2 \int_{0}^{\rho} I(\rho) \rho \, d\rho
\]

and \( N_0 \) is the same as for the RDE.\(^{(77)} \) A plot of \( A(\rho) \) versus \( \rho \) is shown in Figure 51(b).

4.6.1.3 Channel Electrodes

Profile Imaging Downstream from the Electrode Surface. The composition of a solution downstream from a channel-type electrode depends, among other factors, on the rates of heterogeneous electron transfer and homogeneous reactions involving electrogenerated species, and their mass transport characteristics. Information regarding various aspects of these processes can be obtained from the analysis of spectroscopic measurements in which a beam oriented normal to the electrode surface is used to monitor the absorbance of the solution along an axis parallel to the fluid flow. A cell arrangement suitable for this type of measurements is shown in Figure 52.\(^{(78)} \)

Simple Electrode Reaction. In the case of uniform surface concentration, the integrated concentrations profile of the absorbing product \( P \), denoted as \( I \), at a distance \( X \) from the downstream edge of the electrode (\( X > 1 \)) along an axis normal to its surface may be shown to be given by Equation (94):

\[
I(X > 1; \infty) = \int_{0}^{\infty} \theta_P(X, Y) \, dY = \frac{1}{3\nu^3} \Gamma \left( \frac{2}{3} \right)
\times \int_{0}^{1} x^{-1/3}(X - x)^{-1/3} \, dx
\]

Figure 51 Plots of (a) \( I(\rho) \) versus \( \rho \) and (b) \( A(\rho) \) versus \( \rho \) for a transparent ring RRDE.\(^{(77)} \)

with inner, and outer dimensionless radii, \( \rho_1 = r_1/r_0 \) and \( \rho_2 = r_2/r_0 \), respectively, can be shown to be given by

Figure 52 Diagram of a channel cell for spectroelectrochemical studies.\(^{(78)} \)
where \( \theta_p = (D_P/D_R)^{2/3} (C_P/C_R) \). This requirement is fulfilled when the reaction is reversible and, thus, \( C_R \) and \( C_P \) are prescribed by the Nernst equation, or under diffusion limited conditions.

Figure 53 shows plots of current and absorbance versus \( E \) obtained in a solution 0.01 M K₄Fe(CN)₆ in 0.25 M K₂SO₄ recorded simultaneously using a potential scan rate of 1 mV s⁻¹ and a flow rate of 1.74 mL min⁻¹, where the optical monitoring was performed at 1.1 cm from the downstream edge of the electrode. The ordinates of the two curves in this figure are scaled based on the values of \( A \) at \( i_{\text{lim}} \).

Experiments performed under diffusion-limited conditions\(^{80}\) showed that the absorbance as a function of \( X \) for \( X > 1 \) (solid squares in Figure 54), which may be regarded as an image of the integrated concentration profile, was in quantitative agreement with that predicted \( \lambda = 420 \text{ nm} \) along the center axis of the channel in the direction of the flow (solid squares) under diffusion-limited conditions for the oxidation of [Fe(CN)₆]⁴⁻. The solid curve represents theoretical results (the original paper gives full details).\(^{80}\)

**Figure 54** Plot of the steady-state dimensionless integrated concentration profile of [Fe(CN)₆]⁴⁻, generated at the surface of an Au electrode by the oxidation of 0.01 M [Fe(CN)₆]⁴⁻ in 0.25 M K₂SO₄, as a function of the dimensionless distance from the downstream edge of the electrode \( x_2 = x_2/l \). All measurements were performed at \( \lambda = 420 \text{ nm} \) along the center axis of the channel in the direction of the flow (solid squares) under diffusion-limited conditions for the oxidation of [Fe(CN)₆]⁴⁻. The solid curve represents theoretical results (the original paper gives full details).\(^{80}\)
by theory (solid line in the same figure), lending strong support to the validity of the underlying assumptions of the model.

**Determination of the Rate Constant of an Electrochemical–Chemical Mechanism.** Consider a simple EC mechanism of the type shown in Scheme 2, where \( k \) is the rate constant of the homogeneous chemical reaction. Within the framework of approximations specified in section 2.2.2, and assuming \( D_P = D_R = D \), the steady state convective diffusion equations for \( R \) and \( P \) are given in the right-hand panel of Table 5, where the fluid velocity \( U_x \) is given by

\[
U_x = \frac{3}{2} \frac{U}{h} \left( 1 - \frac{(h - y)^2}{h^2} \right) \tag{95}
\]

In Equation (95) \( U \) is the mean flow velocity, and \( h \) is the half-height of the channel.

The appropriate boundary conditions, summarized in the lower section of the same panel, specify that the concentration of the two species is constant over the entire surface of the electrode, which implies that the electrochemical process is infinitely fast. The last entry in that table means that no reactions occur at the optically transparent surface directly opposite to the electrode along the entire length of the channel. This problem, cast in terms of the dimensionless variables \( Y = y/2h, X = x/x_e, C_R = C_{R_d}/C_R, \) and \( C_P = C_{P_d}/C_R \) is given on the right-hand panel in the table.

If \( P \) is the only absorbing species at the selected \( \lambda \), plots of absorbance versus \(-\ln w\), where \( w = (Dx_e)/(24U/2h^2), K = (kx_e)/(6U) \), determined by digital simulations yielded for different \( X \) and \( w/K = 0.01 \), showed clearly defined maxima for each of the curves (Figure 55a). Maxima were also observed for a fixed value of \( X = 1.75 \) and different values of \( w/K \), as shown in Figure 55(b).

Based on these results, an empirical relationship was obtained between the flow rate and the position along the \( x \)-axis at the absorption maxima, \( V_m \) and \( x \), respectively (Equation 96),

\[
\log V_m = \log \left( \frac{2}{3} h^2 x_e b \right) + 1.50 \log k_1 - 0.50 \log D + \log \left( -4.45 + 4.72 \frac{x}{x_e} \right) \tag{96}
\]

where, as before, \( x_e \) is the length of the electrode, and \( b \) the channel width. Hence, it becomes possible to extract values for \( k_1 \) by determining experimentally such maxima using the required physical dimensions of the cell and the electrode, as well as the diffusion coefficient. From a practical viewpoint it is more convenient to fix \( x \)

and measure the relative absorbance for various values of \( V_m \).

Figure 56 shows a plot of \( f/q \), a quantity proportional to the normalized absorbance ratio at two values of \( V_m \), corrected for contributions due to other absorbing species in the media, as a function of \( V_m \), for the oxidation of \( p \)-aminophenol (PAP) to yield \( p \)-benzoquinoneimine (BOI). This latter species undergoes hydrolysis to form benzoquinone (BO). The solid line in this figure represents the best fit to the experimental points. Based on the maximum in this curve, the pseudo-first-order rate constant \( k \) for the irreversible hydrolysis of BOI can be evaluated using Equation (96), yielding values of about \( 0.33 \text{s}^{-1} \).

### 4.6.2 Chronoamperometry under Forced Convection

#### 4.6.2.1 Rotating Disk Electrodes

Consider a chronoamperometric experiment in which the potential of an RDE immersed in a solution containing a nonabsorbing
Table 6 Transient convective diffusion to a RDE

\[

C_R(0, t) = 0 \\
C_R(\infty, t) = C_0 \\
C_R(y, 0) = C_0 \\
\end{array}
\]

Short-time solution

\[
c = \frac{C_R}{C_0}, \quad \tau = (DA^2)^{1/3}, \quad x = \left(\frac{A}{D}\right)^{1/3} y; \quad A = a \left(\frac{v^3}{\nu}\right)^{1/2} \\
\frac{\partial^2 c}{\partial x^2} + \frac{\partial c}{\partial x} = 0 \\
c(0, \tau) = 0 \\
c(\infty, \tau) = 1 \\
c(\zeta, 0) = 1 \\
\]

Long-time solution

\[
\frac{D}{\partial t} \frac{\partial^2 \Theta}{\partial \zeta^2} + 3\nu \frac{\partial \Theta}{\partial \zeta} - \frac{\partial \Theta}{\partial t} = 0 \\
\Theta(0, \theta) = 1 \\
\Theta(\infty, \theta) = 0 \\
\Theta(\zeta, 0) = 0 \\
\]

Dimensionless variables

\[
\Theta = \frac{C_0 - C_R}{C_0}, \quad \theta = \omega \left(\frac{D}{v}\right)^{1/3} \left(\frac{a}{3}\right)^{2/3} \zeta; \quad \zeta = \frac{av}{3D} \left(\frac{v}{\omega}\right)^{1/2} y \\
\]

Convective diffusion equation

\[
\frac{\partial^2 \Theta}{\partial \zeta^2} + 2\nu \frac{\partial \Theta}{\partial \zeta} - \frac{\partial \Theta}{\partial t} = 0 \\
\]

Dimensionless profile

\[
\Theta(\zeta, \theta) = \Theta^{ss} - \Theta^i \\
\Theta^{ss} = \frac{1}{\Gamma(4/3)} \int_0^\infty e^{-\xi} d\xi, \quad \Theta^i = \sum_{n=0}^\infty B_n Z_n(\zeta) e^{\nu^i \xi} \\
B_n = \frac{\nu^{ssn} Z_n(\zeta)}{e^{\nu^i \xi} Z_n(\zeta)} d\xi, \quad B_n = \frac{\nu^{ssn} Z_n(\zeta)}{e^{\nu^i \xi} Z_n(\zeta)} d\xi \\
\]

Dimensionless flux

\[
\frac{j(\tau)}{j(\infty)} = \frac{a^{1/3}}{0.62(\pi \tau)^{1/2}} + \sum_{n=1}^{\infty} \left(-\pi \sum_{k=-3n-1}^{3n-1} \frac{\nu^{n2/2} \lambda^{n2/2}}{\Gamma(-k/2)} \right) \tau^{3n/2} \\
\frac{j(\theta)}{j(\infty)} = -\frac{3a^{1/3}}{0.62} \left(\frac{\partial \Theta^{ss}}{\partial \zeta} \bigg|_{\zeta=0} - \frac{\partial \Theta^i}{\partial \zeta} \bigg|_{\zeta=0} \right) \\
\]

Electroactive species R is stepped from a value \(E_i\), at which no reaction occurs, to a potential sufficiently positive (or negative) \(E_f\) for R to undergo oxidation (or reduction) generating an optically absorbing product, P. According to Beer’s law, the instantaneous change in absorbance \(A\) along \(y\) can be written as

\[
A(t) - A(t = 0) = 2\varepsilon_P \int_0^\infty C_P(y, t) dy \\
(97)
\]

In Equation (97), \(C_P(y, t)\) is the transient concentration profile of P, which can be determined based on the solution of the transient convective diffusion equation subject to the appropriate initial and boundary conditions. Solutions to this problem, for a reactant, have been reported for short times by Krylov and Babak,\(^{(83)}\) in terms of parabolic cylinder functions, \(D_k(\zeta)\), and for long times by Nicancioglu and Newman in terms of (numerically evaluated) eigenvectors and eigenfunctions.
of the associated Sturm-Liouville system. A summary of the two mathematical formalisms, which include the appropriate dimensionless variables and the dimensionless profiles, are given in Table 6. Explicit expressions for the coefficients $b_k(n)$ may be found in the original literature. Exact concentration profiles based on these two solutions spanning a wide range of dimensionless times are shown in Figure 57(a). These were used to calculate the corresponding transient integral profiles involved in the analysis of the spectroscopic data, assuming $D_R = D_P$ (Figure 57b).

Figure 58 shows curves of $[A(t) - A(t = 0)]$ versus $t$ for measurements performed in 0.01 M $K_3[Fe(CN)_6]$ in 0.5 M $K_2SO_4$ aqueous solutions using an Au RDE in the arrangement shown in Figure 45, with the spectrophotometer set at $\lambda = 420$ nm (see Table 4), where the $\varepsilon$ value of $Fe(CN)_6^{3-}$ is very small. Reflection absorption data were acquired at various rotation rates following a potential step from 0.0 to 0.4 V versus Ag/AgCl, which is positive enough for the oxidation of the ferrous species to occur under complete mass transport control. The results obtained for each cycle, consisting of a forward and backward step, were co-added using a signal averager. Also shown in this figure as dotted lines are the theoretical results based on values of $\varepsilon$ for $[Fe(CN)_6]^{3-}$ at 420 nm $= 1.14 \times 10^6$ mol$^{-1}$ cm$^2$, $D = 7.3 \times 10^{-6}$ cm$^2$s$^{-1}$, $v = 0.01$ cm$^2$s$^{-1}$, and the specified rotation rate $\omega$ (radians per second), using the appropriate conversion between dimensionless and actual integral profiles (Equation 98):

$$ (1 - C) d(zt^{1/2}) = \frac{\omega^{1/3}}{2} D^{-1/3}v^{-1/6} c \, dy $$

where $a = 0.51024$. As can be seen, the agreement between theory and experiment for the three rotation rates examined is very good.

4.6.2.2 Channel Electrodes The transient convective diffusion equation governing mass transport of a solution
phase species C in a channel is given by Equation (99):

$$\frac{\partial C}{\partial t} = D \frac{\partial^2 C}{\partial y^2} - v_\text{e} \frac{\partial C}{\partial x}$$  (99)

where $v_\text{e} = (3V/4hd)[1 - (h - y)^2/h^2]$ and other terms have their usual meanings.

Consider a chronopotentiometric experiment in which a potential of large enough magnitude is applied to an electrode in the channel to reduce instantaneously $C_{R}$ to zero at the surface, assuming, that $C_{P} = 0$ before the potential step is applied. The initial and boundary conditions for $R$ and $P$ may thus be summarized as Equations (100–103):

for $t < 0$:  $y = 0, 0 < x < (x_e + x_g + x_d)$,

$$C_R = C_{R0}, C_P = 0$$  (100)

for $t > 0$:  $0 < x < x_e; C_R = 0$,

$$D_R \frac{\partial C_R(y, t)}{\partial y} \bigg|_{y=0} = -D_P \frac{\partial C_P(y, t)}{\partial y} \bigg|_{y=0}$$  (101)

for all $t$:  $y = 0, x_e < x < (x_e + x_g + x_d)$;

$$D_R \frac{\partial C_R(y, t)}{\partial y} \bigg|_{y=0} = D_P \frac{\partial C_P(y, t)}{\partial y} \bigg|_{y=0} = 0$$  (102)

$y = 2h, 0 < x < (x_e + x_g + x_d)$:

$$D_R \frac{\partial C_R(y, t)}{\partial y} \bigg|_{y=0} = D_P \frac{\partial C_P(y, t)}{\partial y} \bigg|_{y=0} = 0$$  (103)

where $x_e$ is the width of the electrode and $x_g$ and $x_d$ are the distances from the downstream edge of the electrode to the area of the solution being monitored optically along an axis normal to the plane of the electrode, as shown in Figure 52.

The time-dependent concentration profiles for all species involved can be obtained by digital simulation techniques, and the values of the parameters then adjusted until a best fit to the experimental data is found. Figure 59(a) shows values of the normalized absorbance for the one-electron oxidation of ferrocyanide, and Figure 59(b) is the reduction of ferrocyanide via chronopotentiometric techniques acquired at wavelengths at which the absorbance of each of the species is maximum. The solid lines in these figures are calculated best-fit curves to the experimental data. Using the value of $D_R$ determined from $i_{\text{lim}}$ (Equation 104),

$$i_{\text{lim}} = 0.925nFwC_{R0} \left( \frac{V_i D_R x_e^2}{h^2 d^2} \right)^{1/3}$$  (104)

for different flow rates and the physical dimensions of the channel, the ratio of the diffusion coefficients of the two species was found to be in excellent agreement with data reported in the literature, i.e. $D_{\text{ferro}}/D_{\text{ferri}} = 1.17 \pm 0.05$.

Application of this method revealed very small differences between the diffusing coefficients of electrogenerated radical species and the neutral precursors in nonaqueous solutions, which suggests that the interactions of the two types of species with the solvent are indeed quite similar.

4.7 Modulation Techniques

Application of an external periodic potential to an electrical system, such as an electrochemical cell, will elicit corresponding periodic variations in the current. Analysis of the amplitudes and phases of the response as

![Figure 59](image_url)
a function of the perturbation frequency constitutes the basis of a general method for the study of the dynamic behavior of electronic circuitry known as impedance spectroscopy. The mathematical treatment of modulation techniques can be simplified considerably by employing periodic signals of a small enough magnitude so that the behavior of the system may be represented in terms of linear equations. This approach allows contributions to the observed signals derived from other sources, such as noise, to be minimized or eliminated, by extracting that component of the response that oscillates at the same frequency as the exciting perturbation. Also amenable to experimental determination are periodic changes in the concentration profiles of species consumed or generated by faradaic processes brought about by the modulating potential, which can be monitored optically by relying either on absorption of UV/VIS chromophores, or on beam-bending effects derived from local changes in the index of refraction along an axis normal to the beam direction.

4.7.1 General Considerations

Consider an experimental arrangement in which light propagating through the solution, reflects at normal incidence from a flat electrode, placed parallel to and at a distance \( d \) from a planar transparent cell window. It will be assumed, for simplicity, that the redox process involves consumption of a nonabsorbing species \( R \), and generation of a single absorbing product \( P \), where both \( R \) and \( P \) are solution phase species, and that only \( R \) is present at the beginning of the experiments. If the attenuation in light intensity induced by other components in the path of the beam, including reflection from the electrode, can be ignored, the intensity \( I \) of the light exiting the cell is given by (Equation 105),

\[
I = I_0 \exp \left( -2\pi k \int_0^d c(y, t) \, dy \right) \tag{105}
\]

where \( I_0 \) is the light intensity entering the cell. Attention is focused hereafter on solutions of one-dimensional mass transport equations of the form

\[
c(y, t) = \tilde{c}(y, t) + \tilde{c}(y, t) \tag{106}
\]

where in Equation (106) \( \tilde{c}(y, t) \) is a slowly varying function of time, or steady state, and \( \tilde{c}(y, t) \) is the oscillatory contribution. Introducing Equation (106) into Equation (105), a normalized absorbance may be defined as follows (Equation 107):

\[
\frac{I}{I_0} = \exp \left( -2\pi k \int_0^d \tilde{c}(y, t) \, dy \right) \tag{107}
\]

Provided that the changes in concentration induced by the periodic perturbation are small, the argument in the exponential can be approximated by the first two terms in the Taylor series expansion, yielding Equation (108) after rearrangement:

\[
\frac{I}{I_0} = \frac{I_{ac}}{I_{dc}} = 2\pi k \int_0^d \tilde{c}(y, t) \, dy \tag{108}
\]

If it is further assumed that the changes in concentration are confined to a volume of solution very close to the electrode surface, \( d \) may be regarded as arbitrarily large, and therefore the upper limit of integration may be set as infinity, leading to much simpler mathematical expressions.

From an experimental viewpoint, the ratio \( I_{ac}/I_{dc} \), can be measured very accurately, such as by using a lock-in amplifier. A quantitative analysis of the results obtained using this modulation technique requires the integral on the right-hand side of Equation (108) to be evaluated, a problem that is equivalent to finding solutions for the mass transport equations subject to the appropriate boundary conditions.

Of particular interest here is derivation of expressions for the oscillatory component of the response of the form

\[
\tilde{c}(y, t) = A^* \Psi(y) \exp(j\omega t) \tag{109}
\]

where \( A^* \) in Equation (109) is the maximum amplitude of the sinusoidally varying concentration, and \( \Psi(y) \) is a function of distance.

4.7.2 Quiescent Solutions

Substitution of Equation (109) into Fick’s second law leads to a differential equation in \( y \) in total derivatives, which can be easily solved analytically to yield Equation (110):

\[
\Psi(y) = \exp \left( -\left( \frac{j\omega}{D} \right)^{1/2} y \right) \tag{110}
\]

Hence, \( I_{ac}/I_{dc} \), also denoted as \( I(\omega t) \), may be written as Equation (111):

\[
\frac{I_{ac}}{I_{dc}} = I(\omega t) = 2\pi k \int_0^\infty A^* \exp \left( -\left( \frac{j\omega}{D} \right)^{1/2} y \right) \exp(j\omega t) \, dy = 2\pi k A^* \left( \frac{D}{j\omega} \right)^{1/2} \exp \left( \frac{D}{j\omega} \right) \tag{111}
\]

that is, the optical response lags the modulated potential by \( \pi/4 \).
In the case of very fast heterogeneous electron transfer reactions, the applied potential prescribes the ratio of concentrations of reactants and products through the Nernst equation. For perturbations of very small amplitude, this equation can be linearized, to yield Equation (112) that relates the amplitudes of the applied potential $E^*$ and those of the concentrations of R and P, $A_R^*$ and $A_P^*$, respectively:

$$E = \bar{E} + E_{dc} + E^* \exp(i\omega t)$$  \hspace{1cm} (112)

where $E_{dc}$ and $E^*$ are given by Equation (113):

$$E_{dc} = E^{\prime \prime} + \frac{RT}{nF} \ln \left( \frac{\bar{c}_R(0,t)}{\bar{c}_P(0,t)} \right);$$

and

$$E^* = \frac{RT}{nF} \left( \frac{A_R^{*2}}{\bar{c}_R(0,t)} - \frac{A_P^{*2}}{\bar{c}_P(0,t)} \right)$$  \hspace{1cm} (113)

Because of conservation of mass at the electrode surface (see Equation 16) $A_P^* = -A_R^*\xi$, where $\xi = (D_R/D_P)^{1/2}$; hence, it becomes possible to express either one of the $A_j^*$ coefficients in terms of $E^*$, to yield Equation (114)

$$E^* = \frac{4RTA_R^*c}{nFc} \cos^2 \frac{a}{2}$$  \hspace{1cm} (114)

where $a$ is given by Equation (115):

$$a = \frac{nF}{RT}(E_{dc} - E_{1/2});$$

and $E_{1/2} = E^{\prime \prime} + \frac{RT}{nF} \ln \left( \frac{D_P}{D_R} \right)^{1/2}$  \hspace{1cm} (115)

The current associated with the faradaic process is related to the flux of material at the electrode surface via Equation (16),

$$i = -nFAD_R \frac{\partial c_R}{\partial y} \bigg|_{y=0} = -nFAA_R^*(\omega D_R)^{1/2} \exp(i\omega t)$$

$$= -nFAA_R^*(\omega D_P)^{1/2} \exp \left( \omega t + \frac{\pi}{4} \right)$$  \hspace{1cm} (116)

where $A$ is the area of the electrode. Hence, from Equations (111) and (116), the current and the optical response are 90° out of phase with respect to one another.

4.7.2.1 Alternating Current Solution-phase Reflectance Spectroscopy  Based on Equations (105) and (109), the ratio of the magnitudes of the current and reflectance signal induced by the modulated applied potential is given by Equation (117),

$$\frac{|i(\omega)|}{|I(\omega)|} = \frac{nFA\omega}{2\kappa k}$$  \hspace{1cm} (117)

and, therefore, for a fixed perturbation frequency, the electrical and optical responses are proportional to each other. In the case of solution-phase redox couples involving at least one UV/VIS chromophore, these considerations afford a basis for implementing a spectroscopic analog of a highly sensitive electrochemical technique known as alternating current (AC) voltammetry. This method relies on the superposition of an AC signal of small amplitude onto a slow linear potential scan, while monitoring the amplitude of the current response. Although restricted to optically absorbing species, this spectroscopic approach offers a definite advantage over current measurements in that the response is not affected by contributions to the electrical signal derived from other sources, particularly double layer capacity effects.

By way of illustration, Figure 60 displays a plot of $I(\omega)$ versus $E_{dc}$ for the oxidation of an unbuffered solution 10 mM $K_4Fe(CN)_6$ in aqueous 1 M KCl obtained at a frequency of 43.9 Hz at a scan rate of 2 mV s$^{-1}$, for which both for the forward and reverse scans, as indicated by the arrows, were found to superimpose. The position of the peak at 0.219 V versus SCE agrees very well with the reversible half-wave potential for the redox couple. Moreover, the width of the peak at half-height was 94 mV, in harmony with that predicted by theory, i.e. 90 mV. This overall behavior is characteristic of the AC response for a reversible one-electron system.

The direct relationship between the optical and electrical response can also be valuable for the determination of rate constants by examining the dependence of the phase angle $\phi$ on the perturbation frequency. In particular, in the absence of effects due to $IR$ drop in the solution, $\phi$ may be shown to be related to the rate of a simple heterogeneous
electron transfer reaction $k_s$ (Equation 118):

$$\cot \phi = 1 + \left( \frac{\omega D}{2k_s} \right)^{1/2}$$  \hspace{1cm} (118)

In fact, a plot of the $iR$-corrected $\cot \phi$ versus $\omega^{1/2}$ (Figure 61) for the ferro–ferricyanide couple obtained from potential modulated spectroelectrochemical measurements was found to be linear, yielding values for $k_s$ around $0.096 \pm 0.008 \text{ cm s}^{-1}$ in agreement with data obtained by more conventional means.$^{(86)}$

### 4.7.2.2 Diffractive Alternating Current Modulation

Light striking the edge of a solid object will be scattered producing a diffraction pattern on a plane normal to the beam direction, including regions in the shadow of the object, with much of the intensity of the diffracted beam originating from areas very close to the edge. Furthermore, the diffracted light will be attenuated by a UV/VIS absorber present very near the edge, and the extent of attenuation will be proportional to the concentration of the absorber therein, as predicted by Beer’s law. Assuming the concentration of product in the area sampled by the diffracted beam, i.e. at and near the electrode edge $C_P^o$ is uniform, the attenuation of the beam may be written as Equation (119):

$$A = \log \frac{I_o}{I_t} = \varepsilon w C_P^o$$  \hspace{1cm} (119)

where $w$ is the electrode length along the optical axis. Furthermore, $I_o$ and $I_t$ are the intensities of the diffracted beam at a specific angle of observation measured before $P$ is generated, and after $C_P^o$ reaches a limiting value, respectively. This situation is somewhat equivalent to that of a conventional spectroelectrochemical cell of a pathlength equal to the length of the electrode along the direction of beam propagation, which can be electrochemically filled or emptied with absorber over a very short period of time.

If $A$ is small, the normalized difference in light intensities $I_o - I_t$, denoted as $\Delta I_{\text{diff}} / I_o$, may be shown to be given by Equation (120):

$$\frac{\Delta I_{\text{diff}}}{I_o} = k_b \xi C_P^o$$  \hspace{1cm} (120)

where $C_P^o = C_P$, $C_R^o$ is the bulk concentration of $R$, and $\xi = (D_R / D_P)^{1/2}$. On this basis, it becomes possible to monitor the modulated diffracted light intensity, and, thus, the concentration of electrogenerated product $P$ in a region of the solution very close to electrode surface. More specifically, the amplitude of the modulated diffracted light intensity $I_{\text{ac}}$ for AC voltammetry is related to the amplitude of the applied voltage by Equation (121):

$$\frac{I_{\text{ac}}}{I_o} = \frac{k_b \varepsilon n F C_P^o E^+}{4RT \cosh^2(a/2)}$$  \hspace{1cm} (121)

As before, this latter expression is valid provided the heterogeneous electron transfer reaction is infinitely fast.

Experiments involving TAA in TEAP/acetonitrile and square wave modulation of relatively large amplitude, i.e. 0.5 V about $E^{\circ}$, yielded values of $I_{\text{ac}}$ lower than those predicted theoretically.$^{(29,87)}$ However, the output of the lock-in amplifier using a modulation frequency of 10 Hz was found to be proportional to the concentration of TAA in the range from $3 \times 10^{-7}$ to $1 \times 10^{-4}$ M. Furthermore, judicious choice of experimental conditions, including higher modulation frequencies, lower angles and phase adjustments, made it possible to increase the detection sensitivity to less than $2 \times 10^{-4}$ M. Also in qualitative agreement with the expected response, were the results of spectroelectrochemical AC voltammetry experiments, which yielded superimposable curves for forward and backward scans for slow scan rates, about 2 mV s$^{-1}$, and $E^+$ value in the range 10–50 mV (Figure 62).

### 4.7.2.3 Transmission Alternating Current Voltammetry

Application of a sinusoidally varying potential to a planar electrode induces a modulation in the concentration of an optically absorbing redox product. Changes along an axis parallel to the electrode surface can be monitored spectroscopically using a CCD or a photomultiplier in
conjunction with a narrow slit to illuminate a small volume of solution. The normalized optically modulated signal may thus be expressed as Equation (122):

\[
\frac{I_{ac}}{I_{dc}} = \varepsilon k w \tilde{c}(y, t) = \varepsilon k w A^* \exp \left( \frac{j \omega}{D} y \exp(j \omega t) \right)
\]

\[
= \varepsilon k w A^* \exp \left( -\frac{\omega}{2D} y \right) ^{1/2} \exp \left\{ \int \left[ \omega t + \frac{\omega}{2D} y \right] \right\} (122)
\]

where \( w \) is the length of the electrode along the direction of light propagation, and \( y \) is the distance normal to the electrode surface. Although results have been reported for a CCD, the most interesting data have been collected with the slit arrangement.\(^{87}\) In particular, Figure 63 shows results for the optically monitored AC spectroelectrochemical voltammogram of TAA obtained for three different scan rates at a distance of 3 \( \mu \)m from the surface, which are similar to those obtained using diffraction as described in the previous section. The expression above indicates that the phase is a function not only of the frequency of the perturbation, but also of the specific distance from the electrode surface.

### 4.7.2.4 Alternating Current Modulated Solution-phase Refraction

According to Fermat’s principle, a beam travelling along an axis \( z \), in a medium in which the index of refraction \( n \) varies normal to the direction of propagation, say \( y \), will bend toward regions having larger \( n \), and that the extent of bending will be proportional to \( \frac{\partial n}{\partial y} \). Assume, more specifically, that \( z \) and \( y \) are parallel and perpendicular to the electrode surface. A modulation in the concentration profile of solution phase species induced by the applied potential will modify the index of refraction along \( y \), and consequently the extent of beam bending. Although refraction is insensitive to the nature of the species that causes the change in the index of refraction, it is useful from a didactic viewpoint to regard these effects as caused by a single species, and that the changes in \( n \) are linear in the concentration of that species, i.e. \( \frac{\partial n}{\partial c} = N \). This situation can be realized experimentally for systems in which a single species is consumed or generated at the electrode surface. On this basis, and neglecting the effects due to the much slower nonoscillatory transient contribution, the oscillatory degree of bending \( \Psi \) will be given by Equation (123),

\[
\Psi = \frac{w}{n} N \frac{\partial c}{\partial y} (123)
\]

where \( w \) is the length of the electrode along \( z \). An explicit expression for the derivative can be obtained from Equations (109) and (110), yielding

\[
\frac{\partial c}{\partial y} = A^* - \left( \frac{j \omega}{D} \right) ^{1/2} \exp \left( -\frac{j \omega}{D} \right) ^{1/2} y \exp(j \omega t)
\]
\[
E = -A^* \frac{\omega}{D} \exp\left(\frac{\omega}{2D} \frac{1}{y}\right) \times \exp\left(j \omega t + \frac{\omega}{2D} \frac{1}{y} + \frac{\pi}{4}\right)
\]

Based on Equations (109) and (124) above, this analysis predicts that \(\tilde{c}\) and \(\frac{\partial \tilde{c}}{\partial y}\) should be 45° out of phase with respect to one another. In fact, large differences in the magnitude of the lock-in amplifier output as a function of phase angle have been reported for potential modulation experiments in solutions containing 0.66 mM TAA and 10 mM BQ, which generate, respectively, an absorbing, and a nonabsorbing product upon oxidation and reduction (Figure 64). This phenomenon makes it possible to enhance the response of the absorbing versus the nonabsorbing product, by simply adjusting the phase angle. This is illustrated in Figure 64(b–d) in the form of amplitude of the measured light intensity at the image plane \(\Delta I_{\text{image}}\), as a function of applied DC potential \(E_{\text{dc}}\) for three different phase angles. Figure 64(a) is the magnitude of the AC current as a function of the applied DC potential, which reflects the much higher concentration of BQ compared to TAA.

4.7.3 Warburg Impedance

The dynamic properties of electronic circuits are customarily defined in terms of a frequency-dependent function known as the impedance, \(Z\) (Equation 125):

\[
Z = \frac{dE}{di}
\]

where \(E\) is the potential and \(i\) the current. It is then possible to define a diffusional impedance, also known as the Warburg impedance, \(Z_w\) as the ratio of the time derivatives of the voltage and the current.

4.7.3.1 Quiescent Solutions

The Warburg impedance for quiescent solutions can be obtained from Equations (112) and (116), namely Equation (126),

\[
Z_w = \frac{\sigma \sqrt{2}}{(j\omega)^{1/2}}
\]

where \(\sigma\) is defined by Equation (127):

\[
\sigma = \frac{RT}{n^2 F^2 A \sqrt{2}} \left(\frac{1}{D_R^{1/2} \tilde{c}_R(0,t)} + \frac{1}{D_R^{1/2} \tilde{c}_p(0,t)}\right)
\]

For a reversible reaction, \(Z_w\) reduces to Equation (128):

\[
Z_w = \frac{4RT}{n^2 F^2 A (j\omega D_o)^{1/2} c_o} \cosh^2 \frac{a}{2}
\]

Based on the results presented in the previous section, the Warburg impedance is in phase with the optical response (see Equation 111).

4.7.3.2 Forced Convection

Expressions for the Warburg impedance of an RDE can be obtained by taking the Laplace transform of the concentration step problem.
as specified in section 2.2.2, and regarding the complex parameter $s$ as $j\omega$.\(^{(89)}\) Plots of the real and imaginary parts of the integral of the concentration profiles as a function of the dimensionless frequency $K$ are shown in Figure 65. These data can also be represented by plotting the real versus the imaginary part of the function in question and specifying the values of the frequency directly on the curve (Figure 66), also known as Cole–Cole or Nyquist diagrams. It is significant to note that for $K > 40$, the angle reaches $-45^\circ$, which implies that at high enough frequencies, the response of the electrochemical system in the presence of forced convection approaches that in a quiescent media.

4.7.4 Determination of Molar Absorptivities of Electrogeneated Species

Provided that $D_R = D_P$, rearrangement of Equation (102) yields Equation (129) for $\varepsilon(k)$ in terms of the integral of the sinusoidal profile:

$$\varepsilon(\lambda) = \frac{I_{\text{ac}}}{I_{\text{dc}}} 2k \int_0^\infty \hat{c}(y, t) dy^{-1}$$

(129)

Setting $I_{\text{ac}} = I^* \exp[j(K\theta + \phi)]$, where $\phi$ is the phase, this equation can be rearranged to Equation (130),

\[\int_0^\infty \text{Im} \Psi \, d\zeta\]

\[\int_0^\infty \text{Re} \Psi \, d\zeta\]
where $A^*$ is the amplitude of the time-varying concentration, and $\gamma$ the factor that converts $y$ into the dimensionless variable $\zeta$. As $\varepsilon(\lambda)$ is real, the phase may be expressed as Equation (131):

$$\phi = \arctan \left( \frac{\Im \Psi d\zeta}{\Re \Psi d\zeta} \right)$$  

(131)

Plots of $\int_0^\infty \Psi d\zeta$ versus $K$, and $\phi$ versus $K$ for an RDE are shown Figure 67.

The most striking verification of the validity of this theory, is provided by the excellent agreement between $\varepsilon(\lambda)$ obtained for ferricyanide from potential modulation spectroelectrochemical measurements (Figure 68) at an RDE in $K_4Fe(CN)_6/0.5$ M $K_2SO_4$ aqueous solutions (see scattered plots), and from conventional transmission experiments given by the continuous curve in the same figure. 

CONCLUDING REMARKS

The quantitative analysis of UV/VIS spectroelectrochemical techniques relies on well-known optical and mass transport principles. Although analytic solutions for transient problems appear to be available only for the simplest of systems, digital simulations involving an inexpensive desk computer provide a means of diagnosing mechanisms and extracting kinetic parameters of interest from experimental data. Furthermore, the advent of computer-controlled instrumentation including data acquisition makes it possible to collect large amounts of information so as to achieve reliable statistics. Intrinsic theoretical and practical limitations imposed by the very nature of these measurements, sets limits on the space-, and time-resolution of absorption-based UV/VIS spectroelectrochemical techniques. Without diminishing its importance and future impact in scientific and technological fields, it seems reasonable to conclude that this specialized subfield of analytical chemistry has reached a solid level of maturity. On this basis, new developments may not be expected in instrumental principles, but in the applications area, especially sensor miniaturization.
ULTRAVIOLET/VISIBLE SPECTROELECTROCHEMISTRY

It may be envisaged that new generations of inexpensive, fully tunable lasers and widespread implementation of chemometrics, will lead to versatile and expedient means for quantitative detection of weak chromophores and thus join the array of existing analytical techniques. Also to be expected over the next few years, are applications of UV/VIS imaging analysis to the study of current distribution in electrochemical cells, which are expected to have an impact on the design of electrochemical reactors for electrosynthesis. It may be interesting to note that in contrast to the absorption-based techniques featured in this article, the analysis of in situ UV/VIS ellipsometric and electroreflectance measurements, continues to pose formidable problems in terms of a quantitative theoretical interpretation. It is hoped that the newly discovered links between electrochemistry and surface science will prompt scientists in both fields to find novel approaches for gaining new insights into the fundamental basis of this phenomenon and thus fully exploit its exquisite surface specificity and sensitivity, which greatly surpasses our theoretical understanding.

1 Introduction

Understanding the electrode/electrolyte interphase is one of the major areas of study in electrochemistry. The structure and properties of the interphase and the interactions both between the electrode and electrolyte, and within the different species in the electrolyte, affect and control the behavior of electrochemical systems. The complex nature of the electrochemical interphase requires the use of different techniques, since a single technique is able to render only a partial picture of the system. The first available techniques, pure electrochemical ones, provided macroscopic information about the reactions occurring at the interphase, and the thermodynamics and kinetics of these processes. It is clear that a complete picture of the interphase cannot be achieved with the information collected by these techniques, since no information about the interactions between the electrode and electrolyte and the interphase structure is obtained.

The existence of a condensed phase in contact with the electrode caused a major problem in using the techniques employed in other fields of surface chemistry, since it constituted a barrier that limited the penetration of the probes. The first approach to studying the surface structure of an electrode was the ex situ approach, using the techniques for surface characterization that the ultrahigh vacuum (UHV) environment provided. Although UHV techniques, such as low-energy electron diffraction (LEED) and Auger electron spectroscopy (AES), are powerful surface characterization techniques, the removal of the electrolyte and the loss of potential control can lead to changes in the structure and

X-ray methods provide an excellent tool for the determination of the structure and composition of the electrode/solution interphase. The possibility of carrying out in situ experiments, because of the low absorbability of the X-rays by the solution, allows direct correlation to be made between the structural changes observed in the sample and the potential applied. Depending on the interaction of the X-rays with matter, these techniques can be classified in two main groups: X-ray absorption techniques and X-ray scattering techniques. Within the absorption techniques, extended X-ray absorption fine structure (EXAFS) and X-ray absorption near edge structure (XANES) will be considered. EXAFS allows determination of the short-range order of the sample, i.e. it provides information about the nature and distances of the closest neighbors to the absorbing atom. On the other hand, identification of the oxidation state of the absorbing atom can be done with XANES. Grazing incident X-ray diffraction (GIXD) and crystal truncation rod (CTR) measurements belong to the scattering techniques. The information obtained from these measurements can be considered complementary since GIXD allows precise determination of the long-range order structure of the interphase whereas CTR analysis gives information about the out-of-plane structure of the interphase. The last technique covered, X-ray standing waves (XSW), is not a pure scattering technique, but rather one that combines X-ray scattering and X-ray interference. With this last technique, the exact position of a foreign atom in the interphase can be determined.

1 INTRODUCTION

Understanding the electrode/electrolyte interphase is one of the major areas of study in electrochemistry. The structure and properties of the interphase and the interactions both between the electrode and electrolyte, and within the different species in the electrolyte, affect and control the behavior of electrochemical systems. The complex nature of the electrochemical interphase requires the use of different techniques, since a single technique is able to render only a partial picture of the system. The first available techniques, pure electrochemical ones, provided macroscopic information about the reactions occurring at the interphase, and the thermodynamics and kinetics of these processes. It is clear that a complete picture of the interphase cannot be achieved with the information collected by these techniques, since no information about the interactions between the electrode and electrolyte and the interphase structure is obtained.

The existence of a condensed phase in contact with the electrode caused a major problem in using the techniques employed in other fields of surface chemistry, since it constituted a barrier that limited the penetration of the probes. The first approach to studying the surface structure of an electrode was the ex situ approach, using the techniques for surface characterization that the ultrahigh vacuum (UHV) environment provided. Although UHV techniques, such as low-energy electron diffraction (LEED) and Auger electron spectroscopy (AES), are powerful surface characterization techniques, the removal of the electrolyte and the loss of potential control can lead to changes in the structure and
ELECTROANALYTICAL METHODS

composition in the interphase. This drawback has limited the application of UHV techniques to the characterization of very stable layers, normally metal layers, on the electrode surface.

In recent years, the advent of in situ spectroscopic scanning probe microscopy (SPM) and X-ray techniques for electrochemical systems have started to fill in the gap in information about the interphase. The spectroscopic techniques, such as in situ Fourier transform infrared spectroscopy (FTIRS) and related techniques,\(^2,3\) enhanced Raman spectroscopy,\(^4–7\) and nonlinear optical spectroscopy,\(^8,9\) give information about the chemical composition and the orientation of the different species on the interphase. The SPM techniques, such as atomic force microscopy (AFM) and X-ray scattering techniques, combines X-ray scattering and X-ray interference. However, interpretation of the images obtained with these techniques is not always straightforward, since the maxima appearing in the image cannot be unequivocally identified with a single species in the system.

Details about the surface structure can also be obtained by X-ray techniques. When compared with SPM techniques, X-ray techniques present several advantages:

- Distances and angles calculated from X-ray measurements have a higher accuracy than those calculated from SPM techniques. The typical error in the distance measurements with STM or AFM is ca. 10%, whereas errors below 2% can be routinely obtained with X-ray techniques. This leads to a better distinction between different possible structures and the detection of small shifts in the positions of the atoms with different experimental conditions.

- Penetration of the X-rays in matter allows collection of data about the surface structure of the electrode, which can also be affected by the experimental conditions. SPM techniques provide information about the outermost layer (only in extreme conditions can the underlying substrate be imaged).

- They can also be used to determine the out-of-plane structure (the structure of the interphase perpendicular to the electrode surface), the short-range order in nonordered interphases, and the chemical nature of the species in the interphase.

The main disadvantage of the X-ray techniques is the requirement of a source bright enough to be surface sensitive. Although some studies have been done using laboratory X-ray sources, their brightness does not allow data about the structure of the interphase to be obtained without very long acquisition times, and a more powerful source has to be used: a synchrotron.

X-ray techniques can be divided into two main families, depending on the interaction of the X-rays with matter: absorption techniques and scattering techniques. Within the absorption techniques,\(^11–14\) we can consider the surface extended X-ray absorption fine structure (SEXAFS), which provides information about the short-range order structure of the substrate, and XANES, which allows identification of the oxidation state of the atoms. The main scattering techniques\(^11–13,15–19\) are GIXD that allows a precise determination of the long-range order structure of the interphase and CTR analysis, a reflectivity technique that gives information about the out-of-plane structure of the interphase. The XSW technique is not a pure scattering technique, but rather one that combines X-ray scattering and X-ray interference. However, in the present article, it has been included as a scattering technique. With this technique, the atomic positioning of foreign atoms in the interphase can be determined.

1.1 X-ray Sources

X-rays were discovered by Röntgen in 1895 using an evacuated tube with two metal plates (anode and cathode). When a voltage is applied between anode and cathode, the residual gas in the tube is ionized and the cations generated collide with the cathode, which releases electrons under this bombardment. These electrons are accelerated by the electric field to the anode and collide with it, generating the X-rays in the sudden deceleration of the electrons. If all the energy of the impinging electrons is converted to X-ray photon energy, the wavelength of the resulting X-rays will be given by the Duane–Hunt law (Equation (1)):

\[
\lambda_{\text{min}} = \frac{hc}{eV} = \frac{12398 \, \text{Å} \, \text{V}^{-1}}{V}
\]

where \(h\) is Planck’s constant, \(c\) is the velocity of light, \(e\) is the electron charge and \(V\) the applied voltage between anode and cathode. (1 Å = \(10^{-10}\) m.) However, not all the kinetic energy of the electrons is transformed into X-ray photon energy. Part of the incident energy can be lost in multiple collisions and inelastic scattering, resulting in a continuous “bremsstrahlung” spectrum (white radiation). Therefore, the wavelength obtained according to Equation (1) (\(\lambda_{\text{min}}\)) represents the minimum wavelength emitted by the tube.

When the accelerating voltage reaches a specific value (which depends on the target material), the electrons are able to knock out a core electron from the atoms of the target material, producing a core hole. If an electron from the outer shells descends to fill this hole, the emitted energy depends on the energy of the two levels involved. This results in a sharp spike in the emission spectrum (Figure 1). These characteristic lines are well defined.
X-RAY METHODS FOR THE STUDY OF ELECTRODE INTERACTION

Figure 1 X-ray spectrum with the characteristic lines emitted by an X-ray tube.

and have an intensity that can be up to three orders of magnitude higher than that of the bremsstrahlung radiation. Thus, conventional X-ray tubes can be used as sources of both a continuous X-ray spectrum and discrete characteristic lines.

The main disadvantage of these X-ray tubes is the low brightness of the generated X-rays. Rotating anode sources, which take advantage of bent crystal optics, are able to generate $10^2$–$10^3$ times higher intensity than a conventional tube. However, the application of these sources to the study of the solid/liquid interphase requires long acquisition times. For that reason, most of the X-ray studies of the electrochemical interphase have been carried out using synchrotron radiation, which provides brightness at least $10^3$ times higher than that obtained with a rotating anode.

1.2 Synchrotron Radiation

The basis of synchrotron radiation is the electromagnetic radiation emitted by a charged particle under acceleration. When a charged particle (in this case, an electron or positron) describes a circular trajectory as a result of a centripetal acceleration, it emits radiation perpendicular to the trajectory. For electrons traveling at low velocity, the radiation is emitted isotropically in all the directions perpendicular to the acceleration, as shown in Figure 2(a). However, at relativistic velocities the radiation is focused into a cone in the plane of orbit of the electrons and in the forward direction (Figure 2b). The divergence angle ($\theta_v$) is approximately inversely proportional to the wavelength and given by Equation (2):

$$\theta_v \propto \frac{1}{\lambda}, \quad \lambda = \frac{E}{m_0c^2}$$

where $m_0$ is the rest mass of the electron.

The radiation emitted by relativistic electrons has a very small divergence (around 0.2 milliradian) which results in a high brightness (defined as the number of photons per unit band width, per unit solid angle, per unit area source) of the radiation. Another important quality of the radiation is that it is almost 100% polarized in the plane of the orbit.

The spectrum of the radiation emitted by a relativistic electron in a circular orbit is continuous down to a critical wavelength, which in turn depends on the energy of the electrons and the radius of the orbit that it follows. The high brightness of continuous radiation allows a specific wavelength to be selected for the experiment without being limited to the characteristic lines of a tube generator. Moreover, the intensity of synchrotron radiation is at least $10^3$ times higher than that obtained by a rotating anode tube.

A synchrotron (Figure 3) is an approximately circular vacuum chamber with bending magnets for directing the beam, quadrupole magnets for focusing the beam...
and radiofrequency cavities for accelerating the electron beam. A synchrotron working properly requires that the energy of the beam be at least 10 MeV. Therefore, a linear accelerator (LINAC) with radiofrequency cavities injects the electron beam continuously in the ring. This classical synchrotron has some disadvantages:

- low stability of the beam;
- the intensity and the critical energy of the radiation changes very quickly depending on the accelerating cycle;
- low beam currents and therefore low intensity;
- the beam is not focused to the extremely small dimensions required by some experiments.

For those reasons, synchrotrons have been replaced by storage rings, which in design are similar to synchrotrons. In these storage rings, the accelerated beam is injected at a given energy, and the machine keeps the beam circulating in the ring for several hours without change in energy. Therefore, the spectrum and the intensity are extremely stable. A radiofrequency cavity is also needed to compensate losses of energy due to the emission of radiation. The electrons circulating in the ring are grouped in bunches, conferring on the beam a time structure which can be used for several experiments, especially in kinetic studies.

In the storage ring, the X-rays are generated in the insertion devices: wigglers, undulators and wavelength sifters. In general, they consist of magnetic structures with alternating poles. As the critical wavelength is proportional to the bending radius, these devices force the electron beam to move with very short radius of curvature. A detailed discussion of the advantage of each insertion device can be found in Wilke.\(^\text{20}\)

### 2 X-RAY ABSORPTION TECHNIQUES

#### 2.1 Interaction of X-rays with Matter

X-rays can interact in two different ways with matter: the X-rays are either scattered or absorbed by the matter. In the first case, the electromagnetic wave of the X-ray beam makes the electrons of matter oscillate, so that they emit radiation in all directions. When no momentum is transferred to the electrons (Compton effect), the scattered beam has the same wavelength as the incident beam. On the other hand, when momentum is transferred to loosely bound electrons, the scattered beam has a higher wavelength than the incident beam. The scattering phenomenon will be discussed extensively in section 3, therefore in this section we will concentrate on the absorption phenomena.

When monochromatic X-rays travel through matter, part of the incident beam is absorbed by it. The intensity of transmitted beam \((I)\) follows the Beer–Lambert Law (Equation 3):

$$I = I_0 e^{-\mu x}$$  \hspace{1cm} (3)

where \(\mu\) is the linear absorption coefficient (which depends on the wavelength), \(I_0\) the intensity of the incident beam and \(x\) the thickness of the sample. Sometimes, Equation (3) is expressed in terms of the mass absorption coefficient \(\mu/\rho\), which is obtained by dividing the linear absorption coefficient by the density \((\rho)\). Therefore (Equation 4):

$$I = I_0 e^{-\left(\frac{\mu}{\rho}\right)x}$$  \hspace{1cm} (4)

The mass absorption coefficient for an element is almost independent of the physical state and approximately additive. This way, the mass absorption coefficient for a compound, mixture or alloy can be expressed as Equation (5):

$$\frac{\mu}{\rho} = \sum_i w_i \left(\frac{\mu}{\rho}\right)_i$$  \hspace{1cm} (5)

where \(w_i\) is the mass fraction of the element \(i\) and \((\mu/\rho)_i\) its mass absorption coefficient. Except for the discontinuities for the absorption edges (see below), the mass absorption coefficient approximately follows the relationship (Equation 6):

$$\frac{\mu}{\rho} = CZ^\alpha\lambda^3$$  \hspace{1cm} (6)

where \(C\) is a constant and \(Z\) the atomic number of the element. For practical uses, values of the mass absorption coefficients are tabulated in Ibers and Hamilton.\(^\text{21}\)
If the energy of the incident beam is increased, it can reach a value where a core electron from an atom in the sample can be ejected, originating an abrupt increase in the absorption coefficient, which is called an absorption edge. There is an absorption edge for each shell and subshell in the excited atom, i.e. there is a K absorption edge, three L edges, five M edges etc. (Figure 4). As expected, the energy of the absorption edge increases in the order \( M < L < K \). After the edge, the diminution in the absorption mass coefficient can also be described by Equation (6), but the constant is different to that obtained at energies below the edge.

Once a hole in the core levels has been created, the excited atom can relax in several ways. First, an electron of the outer shells can descend to fill in the hole, emitting radiation. The energy of this radiation depends on the energy difference between the two levels involved in the electronic transition. This phenomenon is known as fluorescence. The allowed transitions between two electronic levels are restricted to changes in the quantum number of \( \Delta l = \pm 1 \), and \( \Delta m = \pm 1, 0 \). The intensity of the fluorescence signal generated depends on the probability of the transition between the two electronic levels.

The relaxation of the atom can also give rise to the emission of Auger electrons or secondary electrons. In the Auger process, one electron descends to occupy the hole in the core levels, and the energy emitted is used to eject an electron from another level. The secondary electrons are emitted when the Auger electrons or fluorescence radiation interacts with the absorbing atom, ejecting one electron from the outer shells.

When the absorption (or fluorescence) spectrum of a substance is recorded, some oscillations are observed after the edge, superimposed on the decay in absorbance that should approximately follow Equation (6). Figure 5 shows the typical absorbance spectrum of the K edge of a CoO foil. Although the presence of oscillations (EXAFS) was first discovered by Kronig in 1931,\(^{22,23}\) the phenomenon was not fully understood until the 1970s, when Stern, Lytle and Sayers developed their theory.\(^{24}\) From the beginning, it was known that the oscillations contained structural information, since the absorption coefficient for monoatomic diluted gases, for which no interactions between the atoms are expected, showed no oscillations. However, it was not clear whether the oscillations were due to long- or short-range order interactions. The theories developed in the 1970s confirmed that the nature of the oscillations were short-range order interactions.\(^{24–29}\)

The oscillation in the EXAFS region is the result of an interference phenomenon. The electron ejected from the core level can be treated as a wave because of wave–particle duality. In the presence of another atom in the near neighborhood, this wave can be backscattered and interfere with the outgoing wave (Figure 6). From the interference nature of the EXAFS phenomenon, it is clear that the frequency of the oscillations depends on the distance between the absorbing atom and the backscatterer, and the amplitude is function of the nature and number of backscatterers. Therefore, a detailed
analysis of the EXAFS zone can provide information about the short-range order of the sample.

The theories for describing EXAFS are based on the single-electron single-scattering formalism. This assumes that the photoelectron has an energy high enough to suffer only one backscattering event. This condition is normally fulfilled for energies 40 eV above the edge. However, the absorption spectrum of a substance has other regions with important features (Figure 5). Near or below the edge, some absorption peaks may appear, caused by the excitation of core electrons to bond states. The edge position gives information about the effective charge of the absorbing atom, and can be used in the assignment of oxidation states of the atom. In the near-edge region, the photoelectron has a very small momentum and multiple backscattering events take place. All these regions are normally termed XANES. Although the structural information that can be obtained from this region can be very rich, the complex nature of the interaction makes the development of a complete mathematical model difficult. The present status of XANES theory has been reviewed in Bianconi and Stöhr.

2.2 Extended X-ray Absorption Fine Structure and X-ray Absorption Near Edge Structure Theory

As already mentioned, EXAFS refers to the region in the absorption spectrum between 40 and 1000 eV above the edge. In order to obtain the structural information contained in the spectrum, the absorption coefficient as a function of the energy has to be known (\( \mu(E) \)). The first step towards obtaining the structural information is to isolate the oscillatory part of the spectrum from the rest. This process is carried out by subtracting the absorption coefficient obtained for isolated atoms, \( \mu_0(E) \), from the experimental absorption coefficient \( \mu(E) \). \( \mu_0(E) \) could be obtained for a diluted monoatomic gas, since the interactions between the different atoms are very small and the atoms can be considered as isolated. The result is normalized to \( \mu_0(E) \) to obtain the EXAFS function in the energy space (\( \chi(E) \)) on a per atom basis (Equation 7):

\[
\chi(E) = \frac{\mu(E) - \mu_0(E)}{\mu_0(E)}
\] (7)

The dual behavior of the emitted electron allows its wavelength to be calculated from Equation (8):

\[
\lambda = \frac{2\pi}{k}
\] (8)

where \( k \) is the wave vector, calculated according to Equation (9):

\[
k = \frac{2m}{\hbar^2}(E - E_0)
\] (9)

Here \( \hbar \) is \( h/2\pi \), \( m \) is the mass of the electron and \( E_0 \) the energy of the absorption edge. When \( E \) is in eV and \( k \) in Å\(^{-1} \), Equation (9) is transformed to Equation (10):

\[
k = \sqrt{0.2625(E - E_0)}
\] (10)

The structural information of the EXAFS can only be extracted after transformation of the EXAFS function to the wave vector space (\( \chi(k) \)) using Equation (9).

As each shell of atoms surrounding the absorber will give an interference event, the EXAFS spectrum will involve the summation over all these interference events (Equation 11):

\[
\chi(k) = \sum_j A_j(k) \sin(2kr_j + \phi_j(k))
\] (11)

where the subscripts \( j \) and \( i \) refer to the \( j \)th shell of neighboring atoms and the absorbing atom, respectively, \( A_j(k) \) is the amplitude term, \( \sin(2kr_j + \phi_j(k)) \) the oscillatory term, \( r_j \) the distance between the atoms in the \( j \)th shell to the absorbing atom and \( \phi_j(k) \) the total phase shift experienced by the photoelectron. We will discuss each term separately.

2.2.1 Oscillatory Term: \( \sin(2kr_j + \phi_j(k)) \)

This term contains the information about the distance between the backscattering and absorbing atoms. As seen
in Figure 6, the wave travels twice the distance between the absorbing and backscattering atom. Therefore, in the final state, when it returns to the absorbing atom, it has experienced a phase shift of 2krj. However, the backscattering phenomenon is mainly due to the repulsion between the photoelectron and the electronic cloud of the backscattering atom and the effective distance traveled by the photoelectron wave is shorter than 2krj. An additional term, \( \phi(k) \), is required to account for this effect.

2.2.2 The Amplitude Term: \( A_j(k) \)

This term, which contains information about the nature and number of the atoms in the jth shell, can be written as Equation (12):

\[
A_j(k) = \frac{N_j}{kr_j^2} S_j(k) F_j(k) e^{-2\sigma^2_j k^2} e^{-2\lambda_j k} \tag{12}
\]

where \( N_j \) is the number of atoms in the jth shell, \( F_j(k) \) the backscattering amplitude for a single atom, \( S_j(k) \) an amplitude reduction associated to many-body effects, \( \sigma_j^2 \) the Debye–Waller factor and \( \lambda_j(k) \) the mean free path of the electron.

As can be seen, the maximum amplitude, given by \( N_j F_j(k) \), is reduced by a series of factors. The first one, \( 1/(kr_j^2) \), has a double diminution effect. First, the EXAFS function will decrease rapidly as the distance between the absorbing and the backscattering atom increases. This means that the contributions of the farther backscattering atoms to the total EXAFS function will be smaller than those arising from the closer atoms, restricting the EXAFS phenomenon to the closest shells and justifying the short-range nature of the EXAFS. The second damping factor is related to k, implying a diminution of the oscillation amplitude as the energy increases. This is one of the factors that restricts the presence of oscillations to approximately 1000 eV above the absorption edge. Another important factor in the decrease of the oscillations with increasing energy is the Debye–Waller factor (see below).

An additional damping factor is related to many-body effects (\( S_j(k) \)). As the subscript indicates, this term is associated with the absorbing atom and includes losses in the photoelectron energy due to electron shake-up (excitation of other electrons in the absorber) and shake-off (ionization of the electrons of the outer shells).

The reduction in the amplitude due to the thermal vibration and static disorder is contained in \( e^{-2\sigma^2_j k^2} \). When the backscattering event takes place, not all the backscattering atoms in the shell are exactly at the same distance. On the contrary, they may appear displaced from their “equilibrium” positions with a mean standard deviation of \( \sigma_j^2 \). The presence of a negative exponential means that the effect of the Debye–Waller factor is more intense at high-energy values (high k values). The EXAFS spectra of samples with a higher Debye–Waller factor (because of vibrations or static disorder) will exhibit oscillations that disappear rapidly above the edge.

The last damping term corresponds to the inelastic losses in the photoelectron energy (\( e^{-2\lambda_j(k)} \)). The photoelectron that suffers an inelastic loss is not able to contribute to the interference phenomenon. This term is also responsible for the short-range limitation of the EXAFS phenomenon, since the probability of an inelastic loss increases with the distance between the adsorbing and backscattering atoms.

As already mentioned, there is not a complete theory that describes the XANES region of the spectra.\(^{30,31}\) The information contained in this region is mainly related to the absorbing atom. The position of the edge is related to the electronic density of the absorbing atom, in a similar way to X-ray photoelectron spectroscopy (XPS). Other features of the region, such as the so-called “white line” (a sharp peak appearing after the edge) is associated with transitions to unoccupied states. These transitions are also affected by the symmetry of the absorbing atom.

2.3 Data Analysis

In order to obtain the structural information contained in the EXAFS spectrum, the data have to be treated and manipulated. The reliability of the data obtained from the EXAFS spectrum depends on the correctness of the data manipulation. A very detailed data analysis can be found in Teo.\(^{32}\) It normally comprises the following steps:

1. background removal and normalization;
2. conversion to the k space;
3. k weighting;
4. Fourier transforming and filtering;
5. fitting for the phase and amplitude of the filtered spectrum.

We will discuss now in detail every point in the data analysis.

2.3.1 Background Removal and Normalization

Prior to background subtraction, the measured data has to be converted to absorption coefficient. When the measured property is the transmitted intensity, the total linear absorption coefficient can be calculated from Equation (13):

\[
\mu(E)x = \ln \frac{I_0}{I} \tag{13}
\]

Another possibility is to measure the fluorescence intensity (F). As the probability of emitting a photoelectron is
According to Equation (7), the value of \( \mu \) normally followed to calculate beam harmonics, elastic scattering, etc. The strategy background elements, such as the spectrometer baseline, edge jump (\( \mu \)), be known. Normally \( c \) and thus other strategies have to be used to calculate obtained for the Co spectrum. The dashed line represents the additional background is to fit a polynomial spline to the EXAFS part of spectrum. Figure 7 shows the spline obtained is not only \( \mu(\bar{E}) \) but also contains the additional background, thus it is not possible to use it as normalization factor. One of the most used strategies is to divide \([\mu(\bar{E}) - \mu_0(\bar{E})]\) by the edge jump (\( \mu_E \)). Figure 8(a) shows the EXAFS function obtained for a Co film after background subtraction and normalization.

2.3.2 Conversion to \( k \) Space

The conversion to \( k \) space according to Equation (9) requires the determination of the edge threshold (\( E_0 \)). However, the edge position cannot be identified with any feature of the spectrum. Several points can be chosen as the edge threshold, i.e. the onset of the jump, the inflexion point, the mid-point in the edge jump, the edge peak, etc. Despite such an unclear definition of edge threshold, the exact position of the edge is not very important, provided that it is chosen similarly for related compounds. The final analysis of the EXAFS spectrum normally uses comparison with model compounds or theoretical models, in which the value of \( E_0 \) is treated as an adjustable parameter.

2.3.3 \( k \) Weighting

The oscillations in the EXAFS function are attenuated at high \( k \) values by a series of factors. The amplitude of the oscillation has \( 1/k \) factor and normally the backscattering amplitude \([F_j(k)]\) also depends on \( 1/k^2 \). Thus, the oscillations appearing at low energies (low wave vector) dominate over those at high energies. On the other hand, the interatomic distances depend only on the frequency, not on the amplitude of the oscillations. To prevent any effect of the amplitude on the distance determination, the EXAFS function is normally weighted by \( k^1 \), \( k^2 \) or \( k^3 \). \( k^1 \) factor cancels the \( 1/k \) factor in the amplitude functions and \( k^3 \) cancels both the \( 1/k \) and the \( 1/k^2 \) factors. \( k^3 \) is normally preferred for light absorbing atoms and \( k^1 \) for heavy absorbing atoms. When comparing the \( k \) weighted function (Figure 8b) to the original EXAFS function (Figure 8a), it can be seen that the oscillations on the \( k \) weighted function shows a higher relative amplitude for high energies.

2.3.4 Fourier Transform and Filtering

Fourier transform allows the EXAFS function to be translated from the \( k \) space to the frequency (or distance) space (Equation 15):

\[
\phi(r) = \frac{1}{\sqrt{2\pi}} \int_{k_{\text{min}}}^{k_{\text{max}}} w(k) k^n \chi(k) e^{2\pi i k r} dk
\]

where \( w(k) \) is a window function which selects the \( k \) range to be transformed. Fourier transform yields a function that resembles a radial distribution function, in which a number of peaks appear at given distances (Figure 8c). The advantage of Fourier transform is that the transform of a summation of functions is the summation of the Fourier transform of the individual functions. Thus every peak appearing in the radial distribution function can be assigned to a given shell (unless the distances between two shells are small enough to prevent peak resolution in the frequency space). The distance at which each peak appears does not correspond exactly to the distance between the absorbing atom and the shell since
these distances have to be corrected for the total phase shift ($\phi_i(k)$) (see section 2.2). Fourier back transforming the desired shell or shells using a window as shown in Figure 8(c) (dashed line) allows filtering the $k^n\chi(k)$ function and eliminating the undesired contributions (noise, high frequencies...). (Figure 8d).

2.3.5 Fitting for Phase and Amplitude
The last part of the data analysis is obtaining the structural parameters. As shown in section 2.2, the EXAFS function depends on several parameters: $r_j$, $N_j$, $\sigma_j$ and $A_j$. In order to obtain these parameters from the spectrum, the total phase shift ($\phi_i(k)$) and backscattering amplitude ($F_i(k)$) have to be known. One of the usual approaches to calculating both functions is to use the spectrum of model compounds, from which the different parameters are known. Another possibility is to generate these functions from theoretical models, such as the one proposed by Teo and Lee33 or from the program code FEFF34–37.

The use of $\phi_i(k)$ and $F_i(k)$ obtained theoretically or from model compounds implies that they are similar to those found in our spectrum, and this is normally termed as phase and amplitude transferability. The phase transferability is normally regarded as very good, since the phase shift depends on the core electrons of the absorbing and backscattering atoms. Therefore, it is almost independent of the chemical state of both atoms and only depends on their nature. This allows very accurate determination of the interatomic distances, with an estimated error of $\pm 0.01\,\text{Å}$. On the other hand, amplitude transferability is considered worse than the phase transferability, since it depends on several factors. Except when very similar model compounds are used, the determination of $N_j$ is not better than $\pm 20\%$.

The strategy for obtaining the different structural parameters is a nonlinear least-squares fitting with the following function (Equation 16) to the $k^n$-weighted filtered function:

$$Y(k) = \sum_j \frac{N_j}{n_j} F_j(k_j) k_j^{n-1} e^{-2\sigma_j^2 k_j^2} e^{-2r_j^2 / \lambda_j} \sin (2k_j r_j + \phi_j(k_j))$$  \hspace{1cm} (16)
where $F_j(k_j)$ and $\phi_j(k_j)$ functions are obtained from model compounds or theoretical models. Here the value of $E_{0j}$ is allowed to vary for every shell, giving a different $k_j$ value for the shell according to Equation (17):

$$k_j = \sqrt{k^2 - 0.2625(E_0 - E_0)}$$  \hspace{1cm} (17)

### 2.4 Experimental Aspects

#### 2.4.1 Detection

When the X-ray beam interacts with matter, four different processes occur: absorption, fluorescence, Auger electron emission and secondary electron emission. As they are proportional to the absorption coefficient, any of these processes can be used to record an EXAFS spectrum. However, the solvent in the electrochemical cell readily absorbs the Auger or secondary electrons. Therefore, the use of Auger or secondary electrons in in situ electrochemical studies is completely precluded.

The mode of detection is generally dictated by the concentration of the species of interest. In electrochemical environments, we are normally interested in the species in the interphase area, which represent a very small amount of the total number of species in the whole electrochemical system. For that reason, the preferred method of detection is fluorescence using a solid-state detector, which has a high energy resolution and sensitivity. The main drawback of the solid-state detector is the long counting times required to record a spectrum. Total reflection geometry can be used to increase sensitivity. The absorption detection strategy is normally restricted to very porous materials, which have a very high surface-to-volume ratio.

In recording an EXAFS spectrum of a surface species (SEXAFS), it is also important to consider the polarization geometry. Synchrotron radiation is highly polarized in the orbit plane. Because of selection rules, a backscattering event will take place only when the position vector of the backscattering atom has a component in the polarizing plane. The number of neighbors obtained from the spectrum ($N_{\text{eff}}$) is related to the real number of neighbors ($N$) for a K edge according to Equation (18):

$$N_{\text{eff}} = 3 \sum_{i=1}^{N} \cos^2 \alpha_i$$  \hspace{1cm} (18)

where $\alpha_i$ is the angle between the position vector of the i-esim atom and the polarization vector. In-plane (polarization vector parallel to the surface) and out-of-plane (polarization vector perpendicular to the surface) polarization geometries have been used to characterize the exact position of the atoms of an adsorbed layer with respect to the surface atoms.

#### 2.4.2 Time Resolved Extended X-ray Absorption Fine Structure

In a normal EXAFS experiment, the energy of the incident beam is scanned with the use of a monochromator. The time required to cover the full EXAFS region by the monochromator prevents the use of this technique in kinetic studies. The alternative for time resolved studies is the use of dispersive arrangements. In this case, the use of bend optics permits a range of energies to be focused on the sample (normally 600 eV). A photodiode array is employed for the simultaneous detection of the full range and the whole spectrum can be recorded in a millisecond range.

#### 2.4.3 Electrochemical Cell

The design of an electrochemical cell depends on the electrode material and the type of research. There are two main categories, classified by the type of electrode surface: smooth or rough. Figure 9 depicts the basic design used in all the cells employed for smooth electrodes (generally single crystal electrodes). The cell body has two ports for electrolyte exchange, two ports for the counter and reference electrodes and an X-ray transparent polymer film which serves as a window. The polymer film has two positions, inflated and deflated. The deflated position, in which the cell attains a thin layer configuration, is used during the data acquisition. This configuration is required to minimize the scattering due to the solvent. When the electrolyte or potential is changed, the polymer is set in the inflated position, since the equilibrium conditions are reached faster.

A typical cell used in the studies of rough electrodes is depicted in Figure 10. In this cell, the working electrode is set perpendicular to the beam. Unlike the previous cell, this design allows working in absorption or fluorescence mode. The cell is also in thin layer configuration.

A different approach has been used in the study of passive films. In this case, the electrodes were
prepared by sputtering thin films of the electrode material (iron) onto Mylar™ film, in which a thin film of gold or tantalum had previously been sputtered to improve the electrical conductivity. This film is then mounted in the electrochemical cell. The EXAFS and XANES spectra are taken in fluorescence mode, through the back of the electrode (the polymer film). The advantage of this configuration is that the X-ray does not travel through the electrolyte solution, and the electrochemical cell is not restricted to a thin layer configuration. The main disadvantage is that the EXAFS and XANES spectra contain information not only of the electrode surface but also from the bulk electrode material. For this reason, the studies are restricted to thin films.

A complete review of the different cell designs can be found in Sharpe et al.\textsuperscript{[14]}

### 3 X-RAY SCATTERING TECHNIQUES

As mentioned in section 2.1, the X-rays can be absorbed or scattered by matter. In the latter case, the different waves scattered from different atoms can interfere and maxima in the scattered intensity can be obtained at given incident angles. This is normally known as diffraction. However, this is not the only use of the scattering measurements. Additional information can be obtained by studying the scattered intensity in the regions between the diffraction peaks, normally known as CTR and Bragg rods. In the following text, the diffraction and the CTR and Bragg rod measurements will be treated in two different sections. However, the separation is just made for clarity, since both diffraction and rod studies are different ways of measuring the same property: the X-ray scattering.

#### 3.1 X-ray Diffraction

When elastic scattering occurs, the different waves scattered from different atoms can interfere. As the path length is different for each wave, they can interfere constructively or destructively, depending on the incident and scattering angles. In crystalline materials, which have the atoms in fixed positions, the interference phenomenon will give rise to very characteristic diffraction patterns.
A crystalline material is composed of a lattice of identical structural units. Considering a material that has only one atom per unit cell, the position of each atom in the crystal can be found according to Equation (19):

\[ \mathbf{R}_{xy} = x\mathbf{a} + y\mathbf{b} + z\mathbf{c} \]  

(19)

where \( \mathbf{a}, \mathbf{b} \) and \( \mathbf{c} \) are the lattice vectors and \( x, y \) and \( z \) integers. In the Bragg approach, the atoms are considered occupying a set of parallel planes with a \( d \) spacing. A maximum in the scattered radiation will take place when the reflections from successive planes interfere constructively (Figure 11). The difference in the path length for the two waves is \( 2d\sin \theta \). Thus, a constructive interference will occur when this difference be equal to an integral number of wavelengths (Bragg's law) (Equation 20):

\[ n\lambda = 2d\sin \theta \]  

(20)

In X-ray diffraction, it is convenient to define the scattering vector \( \mathbf{Q} = \mathbf{K}_0 - \mathbf{K}_H \), as the difference between the incident (\( \mathbf{K}_0 \)) and scattered (\( \mathbf{K}_H \)) wave vector. In elastic scattering, \( \mathbf{K}_0 \) and \( \mathbf{K}_H \) have the same magnitude \( (2\pi/\lambda) \). Therefore, \( \mathbf{Q} \) is given by Equation (21):

\[ \mathbf{Q} = \frac{4\pi}{\lambda} \sin \theta \]  

(21)

which leads to an alternate expression (Equation 22) for Bragg's law using Equation (20):

\[ \mathbf{Q} = n\frac{2\pi}{d} \]  

(22)

In order to study the X-ray diffraction is useful to employ the Von Laue approach. In the first step it is convenient to define \( \mathbf{Q} \) as a linear combination of the primitive reciprocal lattice vectors, \( \mathbf{a}^*, \mathbf{b}^* \) and \( \mathbf{c}^* \) (Equation 23):

\[ \mathbf{Q} = Q_a\mathbf{a}^* + Q_b\mathbf{b}^* + Q_c\mathbf{c}^* \]  

(23)

\( \mathbf{a}^*, \mathbf{b}^* \) and \( \mathbf{c}^* \) are defined by Equation (24):

\[ \mathbf{a}^* = 2\pi \frac{\mathbf{b} \times \mathbf{c}}{V} \]  \[ \mathbf{b}^* = 2\pi \frac{\mathbf{c} \times \mathbf{a}}{V} \]  \[ \mathbf{c}^* = 2\pi \frac{\mathbf{a} \times \mathbf{b}}{V} \]  

(24)

where \( V \) is the unit cell volume given by \( (\mathbf{a} \cdot \mathbf{b} \times \mathbf{c}) \).

Within the kinematic approximation (also known as the Born approximation), which assumes a single scattering event for the photon, the scattering amplitude (\( A \)) can be calculated from Equation (25):

\[ A = \frac{e^2}{mc^2R} e^{i\mathbf{Q}\cdot\mathbf{r}} d^3\mathbf{r} \]  

(25)

where \( e^2/mc^2R \) is the scattering from a single electron neglecting the polarization factor \( (1 + 1/2 \cos^2 \theta) \), \( R \) is the distance between the sample and detector and \( \rho(\mathbf{r}) \) is the electron density. The total electron density is obtained by summing the electron density for each atom in the crystal (Equation 26), giving a scattered amplitude of:

\[ A = \frac{e^2}{mc^2R} e^{i\mathbf{Q}\cdot\mathbf{r}} d^3\mathbf{r} \sum_{\text{xyz}} e^{i\mathbf{Q}\cdot\mathbf{r}} \]  

(26)

where the atomic form factor \( (f(\mathbf{Q})) \) is the Fourier transform of the atomic electron density \( \rho(\mathbf{r}) \) and the interference function \( (F(\mathbf{Q})) \) is the summation term. Thus (Equation 27), the scattering intensity \( (I) \) is equal to:

\[ I = |A|^2 = A^2 |f(\mathbf{Q})|^2 |F(\mathbf{Q})|^2 e^{-2\pi|\mathbf{Q}|^2} \]  

(27)

where the Debye-Waller factor has been included to account for thermal vibrations. Since in Equation (27), the \( |F(\mathbf{Q})|^2 \) changes rapidly with \( \mathbf{Q} \), the position of the diffraction spots will be given by the maxima in \( |F(\mathbf{Q})|^2 \).

Using Equation (23) the interference function can be written as Equation (28):

\[ |F(\mathbf{Q})|^2 = |F(Q_a, Q_b, Q_c)|^2 \]  

(28)

\[ = \sum_{x=1}^{N_a} \sum_{y=1}^{N_b} \sum_{z=1}^{N_c} e^{2\pi i(xQ_a+yQ_b+zQ_c)} \]  

\[ = \frac{\sin^2 \pi N_a Q_a \sin^2 \pi N_b Q_b \sin^2 \pi N_c Q_c}{\sin^2 \pi Q_a \sin^2 \pi Q_b \sin^2 \pi Q_c} \]  

(28)

where \( N_a, N_b \) and \( N_c \) are the total number of unit cells in the \( \mathbf{a}, \mathbf{b} \) and \( \mathbf{c} \) directions, respectively. This function maximizes (Equation 29) when:

\[ Q_a = h \quad Q_b = k \quad Q_c = l \]  

(29)
with \( h, k \) and \( l \) integers. The position of the diffraction (Bragg) peak is normally termed as \((h, k, l)\). Since \( N_a, N_b \) and \( N_c \) tend to infinity, Equation (28) can be transformed to Equation (30):

\[
|F(Q)|^2 \rightarrow (N_aN_bN_c) \delta(Q_a - h) \delta(Q_b - k) \delta(Q_c - l) = N \delta(Q - Q_{hk})
\]

where \( \delta \) is the Dirac function, \( N \) the total number of atoms in the crystal and \( G_{hkhl} \) is defined as \( ha^* + kb^* + kc^* \). The intensity of the Bragg peak is therefore (Equation 31):

\[
I_{hkhl} = |A|^2 = A^2 |f(Q)|^2 (N_aN_bN_c)^2 e^{-2\pi^2 Q^2}
\]

For ideal crystals, the diffraction pattern consists of perfect \( \delta \)-functions, with infinite value for a Bragg diffraction peak and zero value for the rest of the points of the reciprocal space. However, real crystals present imperfections, defects, grain boundaries, etc. A real crystal can be considered as a set of domains (a lattice of atoms perfectly oriented), in which each domain can have an orientation that differs from the next, giving different diffraction patterns. This results in a broadening of the diffraction peaks. Defining \( \Delta Q \) as the full width at half-maximum (fwhm) of the diffraction peak, the domain size \( (L) \) can be estimated from Equation (32):

\[
L \approx \frac{2\pi}{\Delta Q}
\]

When the unit cell has several atoms, the atomic form factor \( f(Q) \) is replaced by the structure factor defined by Equation (33):

\[
S(Q) = \sum_{j=1}^{n} f_j(Q)e^{iQj}
\]

where \( n \) represents the total number of atoms in the unit cell and the subscript \( j \) the \( j \)th atom in the cell.

When considering diffraction from monolayers and surfaces, they can be treated as a two-dimensional lattice structure, that is, a crystal that has \( N_c = 1 \). Substituting that value in Equation (28) provides the new diffraction conditions (Equation 34):

\[
|F(Q)|^2 = \frac{\sin^2 \pi N_aQ_a \sin^2 \pi N_bQ_b}{\sin^2 \pi Q_a \sin^2 \pi Q_b}
\]

with maxima at \( Q_a = h \) and \( Q_b = k \). No condition is limiting the value of \( Q_c \), so the maxima are obtained regardless of its value. This results in the transformation of the diffraction spots into rods with \( Q_a = h \) and \( Q_b = k \). Such rods are normally termed Bragg rods. This way, the diffracted intensity of the rod will be (Equation 35):

\[
I_{hkhl} = |A|^2 = A^2 |f(Q)|^2 (N_aN_b)^2 e^{-2\pi^2 Q^2}
\]

This equation can be used to calculate the different intensity of the diffraction spots from an adsorbed single layer on a surface. As the diffraction from monolayers and surfaces is independent of the value of \( l \), surface diffraction spots are normally termed as \((h, k)\).

### 3.2 Crystal Truncation Rods and Bragg Rods

The termination of a crystal in a surface or interface will give to the intensity profile some characteristics of the Bragg rods. Thus, the scattered intensity is not zero in the regions connecting two Bragg diffraction spots along directions normal to the surface, giving rise to the CTRs. For a given diffraction peak at \((h, k, l)\), a CTR will occur at \((h, k, Q_z)\). The intensity of such rods can be used to probe the structure of the interphase normal to the electrode surface. Normally, the CTR is measured as reflectivity (defined as the ratio of the integrated reflected intensity to the integrated incident intensity). The integrated intensity is preferred in CTR studies since it is independent of the crystal imperfections and instrumental resolution. Thus, integrating Equation (27) for a given value of \( h, k \) over the angles accepted by the detector, Equation (36) is obtained:

\[
R = T^4(Q_z) \frac{4\pi^2 r_0^2}{\Gamma^2 |k\Gamma|^2 \sin^2 \alpha} |f(Q_z)|^2 e^{-2\pi^2 Q_z^2} \sum_{n=0}^{\infty} e^{iQ_zd_n} e^{-Q_zd_n}
\]

where \( T(Q_z) \) is the Fresnel factor and has been added to account for enhanced surface scattering process, \( r_0 \) the Thomson radius \( (e^2/mc^2) \), \( Q_z \) the projection of \( Q \) in the direction normal to the surface, \( \Gamma \) the area per atom in each layer, \( d \) the layer spacing, and \( \alpha \) the incident angle. The term \( e^{-Q_zd_n \text{abs}} \) accounts for the losses in the intensity due to the absorption of the window material and the thin layer of solvent. This equation has been obtained for equal incident and exit angles. For specular CTR, i.e. when \( \alpha = \theta \) or when \( h = k = 0 \), Equation (36) is converted to Equation (37):

\[
R = T^4(Q_z) \frac{16\pi^2 r_0^2}{\Gamma^2 Q_z^2} |f(Q_z)|^2 e^{-2\pi^2 Q_z^2} \sum_{n=0}^{\infty} e^{iQ_zd_n} e^{-Q_zd_n}
\]

Solving the summation term of Equation (36) gives Equation (38):

\[
\sum_{n=0}^{\infty} e^{iQ_zd_n} = \frac{1}{2 \sin^2 (\pi Q_z)}
\]
The crystal may be reconstructed, the d spacing may be longer or shorter than in the bulk crystal, resulting in a truncation rod that does not follow the dependence on \( \text{sin}^2(Q_z) \). Unlike diffraction, information on the coverage and the species appearing at a given distance from the surface.

A different term has to be added for every different overlayers and surfaces present, the reflectivity can be calculated from Equation (39):

\[
R = T^4(Q_z) \frac{4\pi^2 r_0^2}{\Gamma^2 |k_0|^2 \sin^2 \alpha} |S(Q_z)|^2 e^{-Q_{\text{abs}}^2} e^{-Q_{\text{abs}}^2} \tag{39}
\]

where \( S(Q_z) \) contains the sum over the atomic layers represented by Equation (40):

\[
S(Q_z) = \sum_{n=1}^{\infty} f_{\text{bulk}}(Q_z) \rho_{\text{bulk}} e^{-Q_{\text{bulk}}^2} e^{iQ_z d_{\text{bulk}}} + f_s(Q_z) \rho_s e^{-Q_{s}^2} e^{-iQ_z (d_s - d_{\text{bulk}})} + \sum_{m=1}^{l} \left( f_m(Q_z) \rho_m e^{-Q_{m}^2} e^{-iQ_z (d_m - d_{\text{bulk}} + \sum_{i=1}^{m} d_i)} \right) \tag{40}
\]

Each layer is defined by a Debye–Waller factor (\( \sigma \)), a layer distance from the layer below (\( d \)) and a relative atomic density (\( \rho \)) defined as the ratio of the number of atoms in the \( n \)th layer to the number of atoms in a layer of the bulk material (obviously \( \rho_{\text{bulk}} = 1 \)). The first summation term corresponds to the different layers in the bulk material, the second term to the surface layer and the last one to the overlayers deposited on the surface. In Equation (40), only the topmost layer of the crystal is allowed to reconstruct, expand or contract with respect to the layer structure of the bulk material. Fitting this equation to the experimentally obtained CTR profile will allow determination of the different layer parameters.

CTR and diffraction measurements can be considered as complementary techniques. Whereas diffraction gives the in-plane structure, CTR provides information about the out-of-plane structure, allowing determination of the interlayer distances and of the nature of the species in the layer. The main disadvantage of the CTR measurements is that for complicated systems, the number of adjustable parameters is very high and several sets of parameters can be found that fit the experimental data. In such cases, the CTR measurements only allow some of the possible models for the interphase, proposed according to the diffraction measurements, to be discarded. Moreover, the error in the coverage values given by the CTR measurements is higher than that obtained from diffraction. On the other hand, CTR analysis is not restricted to the presence of ordered layers, unlike diffraction. Information on the coverage and the \( d \) spacing can be obtained for disordered overlayers or surfaces.

For ideal flat overlayers and surfaces, the intensity of the Bragg rods is independent of \( Q_z \). However, real overlayers and surfaces can have atoms with different \( d \) spacing or can be constituted of two different species. In such cases the intensity (or reflectivity) is not constant and depends on \( Q_z \). For such cases, the analysis of the Bragg rods is similar to that used for the CTR measurements, but with a structure factor containing only the terms related to the overlayers (or the surface). A different term has to be added for every different species appearing at a given \( d \) distance from the surface.

3.3 X-ray Standing Waves

Two different phenomena are combined in this technique: diffraction from a perfect crystal and interference. The interference between the incident and diffracted beams creates the standing waves that can be used to probe the position of the foreign atoms in the crystal, or adsorbed on the surface.
When the diffraction theory was considered, the intensity of the diffraction beam was calculated by using the kinematic approach. However, when perfect crystals are to be considered, this theory does not describe the intensity adequately and a dynamic approach has to be used.

In the vicinity of a Bragg diffraction peak, the incident and diffracted beams interfere to generate standing waves. These waves extend up to 1000 Å from the interface in both directions (towards the bulk and the interphase), allowing probing of the interphase and the bulk material. These waves have nodal and antinodal planes that are parallel to the diffracting planes with a nodal wavelength equal to the \( d \) spacing of the diffracting planes. As the angle of incidence is advanced through the Bragg reflection, the relative phase between the incident and diffracted beam changes by \(-\pi\). Owing to this change, the nodal plane moves \( d/2 \) in the direction perpendicular to the surface (Figure 13).

If the energy of the incident beam is set slightly above the absorption edges of the atom we want to study in the interphase, the fluorescence yield of this species will exhibit a modulation as the angle is scanned through the Bragg peak. Analysis of such modulation will serve to determine the distance of the species relative to the surface. However, only one measurement will not be enough to determine the distance \( r \), since two atoms separated by a distance equal to \( d \) would give the same modulation. Therefore, several Bragg diffractions or specular reflections have to be measured in order to unequivocally assign a distance. A complete review on the XSW analysis can be found in Zegenhagen.\(^{56}\)

In some cases, layered synthetic microstructures (LSM) has been used instead of perfect crystals. LSM are periodic structures consisting in alternating layers of low and high electron density materials. These materials have several advantages:

- They can be manufactured with a great variety of \( d \) spacings and materials, allowing the study of the diffuse layer.
- The reflection curves compare well with the dynamic diffraction theory.
- They have a rather large energy band pass.\(^{(11,12)}\)

### 3.4 Experimental Aspects

#### 3.4.1 Four Circle Diffractometer

A four circle diffractometer (Figure 14) is used in order to search all the positions in the reciprocal space in scattering experiments. The sample has three rotational degrees of freedom: \( \theta, \chi \) and \( \phi \) and the detector one, \( 2\theta \). Obviously, there is an indeterminacy in the position in the reciprocal space, since only three rotational degrees are required
to define a position. The degeneracy is solved using an additional constrain in the angle position. For normal operational conditions the $2\theta$ angle is set to be equal to twice the value of $\theta$. This is equivalent to have incident and scattered angles equal. CTR equations were derived in such conditions.

3.4.2 Electrochemical Cell

The cell used in scattering measurements is essentially the same as used in the EXAFS experiments for smooth electrodes (Figure 9). This cell presents the drawback of the thin layer configuration, which makes obtaining kinetic data very difficult. To solve that problem, different cells have been devised and used that do not require a thin layer configuration using a transmission geometry (Figure 15). In these cells, a column of solution surrounded by a polymer film is maintained over the electrode. The counter and reference electrode are then positioned over the working electrode, allowing a much better current distribution over the working electrode. However, the thick column of electrolyte on top of the electrode surface increases the X-ray absorption by the electrolyte and requires the use of the brightest synchrotron sources.

3.4.3 Grazing Incident X-ray Diffraction Geometry

The determination of the in-plane structure of a surface requires the use of surface diffraction techniques. In order to limit the penetration of the X-rays into matter, the incident angle is kept small. With small incident angles, the scattering vector lies predominantly in the surface plane, probing the in-plane structure of the surface or interphase. Grazing incident geometry has several advantages over other possible geometries, such as an increase in the resolution of the surface peaks and a reduction in the background scattering from the bulk crystal.

3.4.4 Diffraction from Overlayers and Surfaces

The case of a crystal ideally terminated is seldom found in nature. The electronic deficiency caused in the topmost layer because of truncation favors the appearance of surface relaxation and reconstruction phenomena. In the simplest case, surface relaxation, the $d$ spacing of the surface layer is altered from that found in the bulk material (maintaining the same lattice in the surface layer as in the bulk layers). Using grazing angle geometry (low $Q_c$), diffraction peaks for the surface can be found at the positions where the CTR are found. As explained in section 3.1, these peaks will correspond to positions where $h$ and $k$ are integers. The surface relaxation can be measured from CTR studies.

When there is a surface reconstruction process, the lattice of the surface layer will be different from that found in the rest of the crystal layers. For that reason, additional diffraction peaks will appear which correspond to the diffraction from the surface. These new diffraction peaks will appear at positions where $h$ and $k$ are not integers (known as noninteger peaks). For each additional noninteger peak, a new Bragg rod will be found, since the surface can be considered as an additional layer. As before, CTR measurements will give the $d$ spacing of the surface layer, and will serve to confirm the diffraction structure proposed according to the diffraction measurements.

The presence of overlayers is similar to that found with reconstructed surfaces. The overlay will give additional diffraction peaks, depending on its lattice. For each lattice peak, Bragg rods will appear. A nice example of the application of Bragg rods to the study of overlayers is found in the work by Toney et al. studying copper underpotential deposition (UPD) on Au(111) electrodes. The analysis of the intensity of Bragg rods served to discriminate the real structure of the Cu UPD from the other structures proposed (see section 4.2.2). As in the previous cases, CTR measurements will give additional information of the surface and overlay structure.
4 APPLICATION OF X-RAY METHODS TO ELECTROCHEMISTRY

4.1 Surface Structure of Metal Electrodes

A logical first step in the interphase studies deals with the surface characterization, especially when single crystal electrodes are used. For single crystal electrodes three different phenomena may take place when the electrode potential is changed: surface reconstruction, expansion or contraction of the topmost layer and surface roughening. For surface reconstruction studies, the best technique is GIXD, since it allows an unequivocal characterization. For reconstructed surfaces, it is logical to expect an interlayer distance different to that found in bulk material, especially in the cases where the atomic surface density is different to that observed in the bulk layer. CTR studies can be used to measure the interlayer distance, jointly with the atomic density of the surface layer. CTR studies can also be used to measure surface roughness.

4.1.1 Au(111) Electrodes

Unlike most of the (111) planes of the face-centered cubic (fcc) crystals, the Au(111) surface reconstructs. The studies of this electrode surface can be used as a model of the information that can be obtained from the system using X-ray techniques. The first point to determine is the nature of the reconstruction and its stability range.

In UHV environments, the reconstruction leads to the formation of a $(23 \times \sqrt{3})$ structure (also called herringbone reconstruction) with an increase in the atomic surface density of 4.4%. In electrochemical environments, there is an additional variable, the electrode potential, and the reconstruction can be sensitive to changes of potential. In this particular case, the reconstruction is found to be potential dependent. Below a critical potential, which is always more negative than the potential of zero change (p.z.c.), the structure found in three different electrolytes (0.01 M NaF, NaCl and NaBr) is the same as that found in the UHV environments: the $(23 \times \sqrt{3})$ surface structure (Figure 16). Above this potential, the reconstruction is partially lifted to give a $(p \times \sqrt{3})$ structure with $23 < p < 30$. At potentials positive to the p.z.c., the reconstruction disappears and the $(1 \times 1)$ surface structure is found. The phase transition between the $(23 \times \sqrt{3})$ and the $(1 \times 1)$ structure is reversible, that is, at a given potential the surface structure obtained is the same, irrespective of the initial conditions.

The kinetics of the phase transition can be obtained following the time evolution of the peak intensity of the reconstructed surface. It was shown that the transition to the $(1 \times 1)$ phase is much faster than the formation of the reconstructed phase. Dependence in the rate of the phase transition with the anion present in the electrolyte was also observed. Chloride and bromide anions accelerate the transition, whereas the presence of pyridine, 2,2'-bypiridine and uracil slows down the phase transition.

Finally, the expansion or compression of the topmost layer was studied by CTR measurements. The presence of a reconstructed surface (which has a higher atomic density than the bulk layer) leads to an expansion of the interlayer distance for the reconstructed surface, i.e. the $d$ spacing has increased 3.3% with respect to that found in the bulk material. No change in the distances was observed for the $(1 \times 1)$ structure.

4.1.2 Au(100) Electrodes

The general behavior of the Au(100) electrode is similar to that described for the Au(111) electrode.
At negative potential with respect to the p.z.c., the surface layer exhibits an hexagonal reconstructed surface, whereas at positive potentials, the (1 × 1) structure is found. The hexagonal reconstruction has an atomic surface density 22% greater than that found in the bulk Au(100) layer. This reconstructed phase is the same that was found in UHV environments. When the reconstruction is lifted at positive potentials these excess of atoms is segregated to an additional layer. This new layer has an atomic surface density that corresponds to 22% of the bulk layer. In perchloric acid, a partial reconstruction is observed at potentials negative to 0.4 V vs a standard calomel electrode (SCE).  

4.1.3 Pt(111) and Pt(100) Electrodes

No evidence of reconstruction has been found for these surfaces in electrochemical environments. In these surfaces, the effect of the anion and hydrogen adsorption in the relaxation/contraction of the topmost layer and the effect of oxide formation has been studied.

4.2 Adsorbed Layers on Metal Surfaces

One of the most studied phenomena in surface electrochemistry in recent years is the UPD of metals. The UPD process is mainly controlled by the interaction between the depositing metal and the electrode surface. However, the anions present in the electrolyte also play an important role in this process since the interaction of the anions with the electrode surface and with the depositing metal affects the whole UPD process. Therefore, it is essential to understand the process of anion adsorption on the bare surface.

4.2.1 Anion Adsorption on Single Crystal Electrodes

Studies of anion adsorption on single crystal electrodes have focused mainly on halide adsorption. These studies highlight the influence of the surface structure and nature on the electrode. A clear example of that is the adsorption of iodine on Au(111), Ag(111) and Pt(111) electrodes. For Au(111) and Ag(111) electrodes, iodine adsorption exhibits very complex behavior. The first structure observed is a (3√3 × √3) R30° (only present in Ag(111) electrodes). As the potential is made more positive, the structure changes to a uniaxial incommensurate structure, c(p × √3), where p decreases with the potential. Finally, the structure changes to a rotated incommensurate hexagonal phase. On the other hand, Pt(111) electrodes exhibit completely different behavior. Only two commensurate different phases are observed: (3 × 3) and a (7 × 7)R 21.8°. Moreover, the I–I distance obtained is smaller in Pt that in Au or Ag, clearly the result of a stronger Pt–I interaction. The UPD peak was more difficult and was, for some time, the SEXAFS measurements provided an accurate determination of the Cu–Cu distance in this structure (2.92 ± 0.03 Å, 2.89 ± 0.03 Å). This value is the same as the Au–Au distance in the (111) plane (2.88 Å), implying that a Cu(1 × 1) adlayer is commensurate with the Au(111) substrate. In this structure, Cu adatoms probably sit on threefold hollow sites, as derived from the SEXAFS spectra. The SEXAFS spectra also indicate the existence of oxygen (likely arising) from (bi)sulfate on the Cu adlayer in which Cu presents a +1 oxidation state. The determination of the structure after the first UPD peak was more difficult and was, for some time,
found that the Cu adlayer, at intermediate coverage values, was not imaged by Toney et al. using X-ray CTR measurements. As was the case for the Cu-(1 × 1) structure, XANES clearly suggested that the oxidation state of the Cu adatoms after the first UPD peak is approximately +1, again probably as a result of a polar bond or surface dipoles. For this structure, it has been proposed that the Cu adatoms occupy on-top positions.

The voltammogram of Cu UPD in presence of chloride shows two pairs of peaks, as in the case of sulfuric acid, but the pair at high underpotentials is reversible and appears at potentials that are more positive than in sulfuric acid. The second pair of peaks almost overlaps with bulk Cu deposition. After the first peak, a bilayer structure was proposed after SEXAFS measurements, in which chloride is adsorbed on the copper (θCu = 0.62) and the copper atoms are in registry with the top layer of chloride ions. The distances in the proposed structure are quite similar to those found in solid CuCl.

In the presence of bromide, the behavior is very similar to that found in the presence of chloride, with a predicted bilayer structure. Recent X-ray scattering studies revealed the presence of an ordered hexagonal bromide adlayer at the onset of copper deposition. This adlayer undergoes a phase transition to form a (4 × 4) commensurate structure (θBr = 0.56) at the peak at 0.32 V vs Ag/AgCl. The bromide adlayer remains stable until bulk copper deposition. Copper is deposited in-between the gold surface and the bromide layer. As a general trend for all Cu–halide adlayers, the structure of these adlayers is governed by the halide–halide and the Cu–halide interactions in contrast to the Cu–(bi)sulfate adlayers in which the Cu–Au interaction is dominant. However, all interactions contribute to the UPD processes.

On Au(100) electrodes in sulfuric acid media, Cu UPD occurs in a relatively broad peak. STM studies showed that the surface structure after the deposition peak is a pseudomorphic (1 × 1) structure in which the Cu atoms occupy the fourfold hollow site. XSW measurements also indicated that the Cu adatoms occupy the fourfold hollow site. However, SEXAFS measurements suggested a different picture of the adlayer at full coverage. In the model proposed according to the experimental data (which is incompatible with STM and AFM images), the Cu–Cu distance is shorter than the Au–Au distance in the unreconstructed Au(100) surface and the Cu adatoms occupy the a-top sites. This would imply that the topmost gold layer is rearranged or reconstructed. As on Au(111) electrodes, the Cu oxidation state is close to +1.
4.2.3 Lead Underpotential Deposition on Au(111) Electrodes

Lead and gold have very different atomic sizes (lead is ca. 20% larger than gold), which favors the formation of incommensurate adlayers. In fact, at potentials negative of the main UPD peaks, a hexagonal incommensurate structure has been found using X-ray diffraction techniques.\textsuperscript{(108,109)} This structure was also observed by SPM.\textsuperscript{(110–113)} In this structure, the lead–lead distances are compressed 0.7% with respect to bulk lead.\textsuperscript{(108,109)} The lead adlayer is rotated with respect to the Au(111) plane with an angle which varies between 2.5° and 0° depending on the applied potential (Figure 19).\textsuperscript{(109)} which is consistent with the change in lead–gold distance over the same potential region observed with another X-ray diffraction technique.\textsuperscript{(114)}

4.2.4 Mercury Underpotential Deposition on Au(111) Electrodes

The behavior of the mercury UPD on Au(111) electrodes resembles in some cases that of copper UPD on the same electrodes. The voltammetric profile of mercury UPD on Au(111) electrodes in 0.1 M H₂SO₄ shows several pairs of peaks. The voltammogram shows a main deposition/stripping peak (centered at around +0.90 V vs Ag/AgCl) that splits into two. The initial stages of mercury UPD appear to trigger an order–disorder transition in the (bi)sulfate adlayer that gives rise to the first pair of peaks.\textsuperscript{(115)} After the second pair of peaks an ordered surface structure is found. STM measurements have shown the existence of two different ordered structures after this peak.\textsuperscript{(116)}

\[
\begin{pmatrix}
2 & 0 \\
3 & 2/3
\end{pmatrix}
\quad \text{and} \quad
\begin{pmatrix}
1 & \bar{1} \\
4 & 4
\end{pmatrix}
\]

The first structure was later observed by in situ X-ray diffraction and identified as a \((\sqrt{3} \times \sqrt{3})\) surface structure.\textsuperscript{(117)} CTR measurements indicated that the adlayer is probably constituted by Hg₂⁺⁺ cations and (bi)sulfate anions.\textsuperscript{(117)} Based on the atomic distances derived from the CTR measurements, an adlayer structure similar (although distorted) to the honeycomb...
structure observed for copper UPD in the same medium was proposed. At \(+0.82\) V vs Ag/AgCl, the ordered structure disappears. 

Apart from the surface processes of mercury UPD, a process controlled by diffusion also appears in the voltammogram at potentials around +0.54 V vs Ag/AgCl. This redox reaction corresponds to the oxidation–reduction of mercury species in solution according to Equation (41):

\[
2\text{Hg}^{2+} + 2e^- \rightleftharpoons \text{Hg}_2^{2+} \quad E^o = +0.698\text{ V vs Ag/AgCl}
\]

Coinciding with this diffusion-controlled process other additional ordered structures have been found. AFM measurements have identified a hexagonal structure at these potentials. 

X-ray diffraction studies identified two different hexagonal adlayers in this region: one at potentials between +0.63 and +0.68 V (vs Ag/AgCl) with a Hg–Hg distance of 3.84 Å, and another at potentials below +0.63 V (vs Ag/AgCl) with a Hg–Hg distance of 3.33 Å. The first hexagonal adlayer appears to be metastable and evolves, with time, to give the second adlayer.

The effect of anions is also evident in the case of mercury UPD. Unlike copper UPD, the voltammetric profile for mercury UPD on Au(111) in the presence of chloride resembles that observed in sulfuric acid media alone. This would indicate that in both chloride and sulfuric acid media the UPD process is governed by the mercury–substrate interactions. After the main UPD peaks, CTR measurements showed that a Hg₂Cl₂ bilayer is formed, in which mercury is bonded to the gold surface and chloride is deposited on top of the mercury adatoms. In acetic acid media, hexagonal structures have been observed with X-ray diffraction after the main UPD peak.

### 4.2.5 Copper Underpotential Deposition on Pt(111) Electrodes

EXAFS studies have shown that the copper layer in sulfuric acid media is not completely discharged on the surface at potentials after the UPD peak. The charge of the copper species on the Pt(111) surface is close to +1 and not zero as expected based on complete charge transfer, while the platinum surface retains some negative charge, as in the case of Au(111) electrodes. At full coverage, EXAFS results show that the copper layer has a close-packed structure with a copper–copper distance of 2.77 ± 0.03 Å. This structure corresponds to the copper residing in the threefold hollow sites of the Pt(111) surface. GIXD and CTR measurement have determined that the UPD process of copper on Pt(111) electrodes is very similar to the one taking place on Au(111) electrodes. The first step in the UPD process is the formation of the honeycomb structure, followed by the formation of a full copper monolayer with (bi)sulfate anions adsorbed on top of the copper layer.

Bromide and chloride anions also show a dramatic effect upon copper UPD onto platinum single crystals. In both media, the deposition and stripping again take place in two distinct steps on Pt(111), in which copper retains a partial charge. In chloride media, GIXD measurements showed that the adlayer presents a Bragg rod at the (0.765, 0, L) position after the first UPD peak, which corresponds to the formation of an incommensurate hexagonal CuCl adlayer (Figure 20). After the second UPD peak, a commensurate (1 x 1) copper adlayer forms on the electrode surface, which, in turn, is covered by a disordered layer of chloride anions. In this adlayer, SEXAFS findings also indicated that in the presence of chloride, the copper–copper bond distance of the deposited layer was close to that of bulk copper, unlike that of copper deposited in the absence of chloride. The kinetics of the phase transitions between the incommensurate and the (1 x 1) structures were followed by GIXD. These studies revealed that the transition from the (1 x 1) structure to the incommensurate structure occurs through a two-step mechanism. In the first step, the copper is desorbed which gives rise to the current response. On a much longer timescale, the reorganization of the layer takes place to give an ordered CuCl bilayer.
In bromide medium, an incommensurate hexagonal structure aligned along the (1,0) surface direction is observed by GIXD after the first UPD peak, corresponding to a CuBr layer with an interatomic distance of 3.74 Å. At potentials negative of the second UPD peak, it has been proposed that copper forms a (1 × 1) structure, which is, in turn, covered by a disordered bromide layer.

4.2.6 Lead Underpotential Deposition on Ag(111) Electrodes

Attempts to elucidate the structure of lead adsorbed on Ag(111) have been done using surface X-ray scattering techniques. Deposition from either perchloric acid or acetate media shows the presence of peaks in the azimuthal scans (varying φ angle) at

\[ \phi = \pm 4.5^\circ \] \(^{(109, 134, 135)}\) This marks the presence of two equivalent domains of an incommensurate lead overlager that are each \(-4.5^\circ\) from the Ag[011] direction as confirmed in the STM measurements\(^{(138–140)}\). GIXD measurements have also shown that lead deposited onto Ag(111) at full monolayer coverage undergoes a compression of 1.4% relative to bulk lead\(^{(134–136)}\). The compression increases linearly with applied potential until the onset of bulk deposition where the compression is 2.8%. X-ray studies done employing surface differential diffraction have found that the distances measured for the lead layer were between 3.00 ± 0.05 and 3.2 ± 0.1 Å\(^{(137)}\). These distances can be ascribed to lead atoms being adsorbed between the a-top and the bridge sites.

In situ EXAFS has been performed in acetate media\(^{(141)}\). These studies have found that the deposited lead is in a zero-valent state and that the lead layer is incommensurate to the silver substrate. There is also scattering observed from an oxygen atom, which is most likely coming from the water or acetate. This scattering implies that these molecules are adsorbed on the deposited lead layer.

4.2.7 Thallium Underpotential Deposition on Silver Single Crystal Electrodes

GIXD studies of thallium UPD on Ag(111) have shown that after complete deposition of one monolayer, there is an incommensurate, hexagonal structure on the surface\(^{(109, 142, 143)}\). This structure is compressed relative to bulk thallium by 1.4–3.0% and rotated from the Ag[011] direction by \(\Omega = 4–5^\circ\), depending on potential\(^{(109, 142, 143)}\). Vapor deposited thallium in UHV presents the same structure, suggesting that the solvent molecules do not affect the deposition structure\(^{(143)}\). Upon completion of deposition of the second monolayer, the thallium forms a bilayer that has also an incommensurate hexagonal structure\(^{(109, 142, 143)}\). The second layer is commensurate with the layer beneath it and the newly deposited thallium atoms sit in the threefold hollow sites of the bottom layer\(^{(143)}\). In this structure, the compression is 1.0% relative to bulk thallium and the rotation is 3.9\(^\circ\)\(^{(142, 143)}\).

Thallium deposition onto Ag(100) has also been studied by surface X-ray scattering\(^{(144)}\). A disordered phase is formed after the first voltammetric peak, whereas an ordered monolayer is obtained after the second voltammetric peak. This layer has a c(p × 2) close-packed structure which compresses uniaxially (p decreasing from 1.185 to 1.168) with decreasing potential\(^{(144)}\). With deposition of the second layer, it has been found that the first layer expands slightly and both layers form a c(1.2 × 2) bilayer.
X-RAY METHODS FOR THE STUDY OF ELECTRODE INTERACTION

4.3 Fuel Cell Electrodes

Most fuel cells use platinum as an electrode material (especially for the hydrogen fuel cell and the direct methanol fuel cell). The high cost of platinum makes the dispersion of the metal on a supporting material such as carbon advisable in practical applications. On some occasions, platinum has been alloyed in order to increase its catalytic activity towards the desired reaction.

The dispersion of platinum creates small particles that can have different electrocatalytic properties than the bulk material. The first studies carried out confirmed that the platinum oxide formed at positive potentials has a short-range structure similar to \(\alpha\)-PtO\(_2\).\(^{145}\) Alloying the platinum resulted in a diminution in the \(d\)-band occupancy with respect to the platinum particles and a contraction in the Pt–Pt distances.\(^{146}\) All the alloys studied showed an increase in the catalytic activity for the oxygen reduction except the PtMn/C alloy. A volcano type correlation was found between the Pt–Pt distance and the \(d\) band occupancy with the electrocatalytic activity for oxygen reduction. In contrast to the oxygen reduction, the electrocatalytic oxidation of hydrogen shows no significant differences between Pt and the Pt alloys, indicating that the structural parameters and \(d\) band occupancies have no effect on the reaction.\(^{147}\)

For Pt particles, structural changes are observed upon hydrogen adsorption, whereas the alloy particles exhibit no changes.\(^{147,148}\) These changes in the Pt–Pt distance and in the Pt coordination number have been attributed to a reversible reconstruction that takes place upon hydrogen adsorption.\(^{148,149}\)

The effect of the Pt particle size has been investigated in relation to methanol oxidation. The EXAFS and XANES results show that the reduced activity towards methanol oxidation is the consequence of a stronger CO and OH adsorption in the small particles.\(^{149}\) The strong OH adsorption also results in a lower activity towards oxygen reduction. The size effect of particle size has also been studied for Cu and Pb UPD on carbon-supported platinum.\(^{150–152}\)

Pt–Ru particles exhibit an increase in the catalytic activity towards methanol oxidation due mainly to a bifunctional mechanism in which the Ru atoms facilitated the removal of the CO species. This effect has been confirmed by XANES, which shows no change in the oxidation state of the Ru atoms when CO is present in the solution for potentials at which the oxidation of ruthenium takes place in absence of CO.\(^{153}\) The presence of Ru in the alloy diminishes the Pt–Pt distances and diminished the \(d\) band occupancy, a clear indication that the Ru has also an electronic effect on the platinum particles.\(^{154}\) The formation of RuOH species in the alloy takes place at 0.24 V vs SCE.\(^{154}\)

4.4 Battery and Oxide Electrodes

Oxidation of Ni(OH)\(_2\) has been extensively studied by EXAFS and XANES.\(^{155–161}\) The uncharged material (\(\beta\)-Ni(OH)\(_2\)) shows changes in the (0001) plane of the Ni(OH)\(_2\) with charging–discharging cycles.\(^{157}\) The charge material corresponds to a nickel oxide in an oxidation state of ca. +3.5, determined by using the edge position and the distances and coordination numbers of the oxygen atoms.\(^{159}\) The structure of the charged material showed two different Ni–O interactions at 1.88 and 2.07 Å and with coordination numbers of 4.1 and 2.2 respectively, and two Ni–Ni interactions at 2.82 and 3.13 Å with coordination numbers of 4.7 and 1.0 respectively. The longer Ni–O interactions were interpreted as Ni–OH distances and the shorter were attributed to Ni–O in tetravalent nickel compounds. The same oxidation state has been obtained by simulating the near edge part of the spectrum with the FEFF6 code program.\(^{160}\) Oxidation of \(\alpha\)-Ni(OH)\(_2\) also gives nickel oxides with an oxidation state of 3.5.\(^{161}\)

Additional studies have been conducted with \(\nu\)\(_2\)O\(_5\) electrodes,\(^{162}\) CuO\(_2\) electrodes,\(^{163}\) PbO\(_2\)\(^{164}\) and Li\(_x\)Mn\(_2\)O\(_4\).\(^{165}\)

4.5 Corrosion

The nature of the passive film formed on iron electrodes has been investigated with in situ XANES in borate buffer solution. Comparison with model compounds indicates that the structure of the oxide passive film is \(g\)-Fe\(_2\)O\(_3\)/Fe\(_3\)O\(_4\).\(^{150}\) Diffraction studies of the passive film have been used to discriminate between the two possible structures.\(^{166}\) Calculating the theoretical structure factors for different structures and comparing them with those obtained from diffraction measurements, allowed the identification of the structure of the passive film. The film structure is based on the structure of Fe\(_3\)O\(_4\), but with cation vacancies on the tetrahedral sites and octahedral sites and cations occupying the interstitial octahedral sites. The oxidation state of iron in the passive film is mainly Fe\(^{3+}\), with a Fe\(^{2+}\) proportion that oscillates between 4 and 20% depending on the applied potential.\(^{167}\) When the passive film was obtained at potentials below −0.6 V vs mercury sulfate electrode (MSE), dissolution is observed during the first stages of the film formation.\(^{167}\) The cathodic dissolution of the passive films was studied using Fe\(_2\)O\(_3\) and Fe\(_3\)O\(_4\) films.\(^{168}\) The reduction of the Fe\(_2\)O\(_3\) film takes place in a two-step mechanism. In the first step, the Fe\(_2\)O\(_3\) is reduced to Fe\(_3\)O\(_4\) with partial dissolution. In the second step, the formed Fe\(_3\)O\(_4\) film is reduced to Fe\(^{2+}\). The dissolution of the passive film depends on the solubility of the Fe\(^{2+}\) species. Thus, in basic media no dissolution is observed, owing to the insolubility of Fe(II) species. In borate buffer, dissolution is only observed.
during step 2. The anions also affect the dissolution rate of the passive film. During anodic dissolution, chloride anions accelerate the dissolution when compared to sulfate anions, as a result of the complexation of Fe cations by chloride anions.\textsuperscript{(169)} Cathodic dissolution does not show any dependence on the anions. The effects of the presence of Cr and other additives to iron have also been studied.\textsuperscript{(170–172)} These studies showed the presence of Cr(IV) at positive potentials.

The addition of chromium confers corrosion resistance to passive films. For that reason, it has been used extensively in aluminum alloys. The XANES studies indicate the possibility of oxidizing the initial Cr(III) to Cr(VI).\textsuperscript{(49,173,174)} Depending on the experimental conditions, the Cr(VI) species are stable on the passive film and can be reduced to the initial oxidation state. The Cr(VI) species accumulate on the outer region of the passive film. Owing to the toxicity of chromium, cerium oxides have been used as a possible substitute in passive films. XANES studies indicate that cerium is in an oxidation state of +3.\textsuperscript{(175)}

\section*{4.6 Other Examples}

Several studies have been conducted on polymer electrodes modified with several salts\textsuperscript{(176–181)} and modified electrodes.\textsuperscript{(182–185)} These studies focus mainly in the determination by EXAFS of the short-range structure around the metallic atom in the polymer or modified electrodes.

1 Introduction
1.1 History of Luminescence

In order for the luminescence process to exist for any period of time, energy must be supplied to the system to maintain an excited state population. Different forms of luminescence have been classified based on the source of this energy. While several interesting forms of luminescence exist (e.g. electroluminescence, bioluminescence, radioluminescence, triboluminescence and sonoluminescence), this discussion will focus on the type of luminescence that is of analytical importance, i.e. photoluminescence. In photoluminescence, the excited state is produced by the absorption of light.

Luminescence processes can further be categorized as fluorescence or phosphorescence. This distinction is based on the multiplicity of the two energy levels involved in radiative deactivation from the excited state. If the electron spin states of the two energy levels are the same, the process is referred to as fluorescence. In contrast, if the spin states are not the same, the process is properly called phosphorescence. The distinction and consequences of these differences will be discussed in further detail in section 3.1.

Fluorescence spectroscopy has several analytical advantages over spectroscopic methods such as absorption spectrometry. The most significant are selectivity and sensitivity, which are inherent to the technique. The selectivity arises from the fact that both the absorption and emission occur at specific wavelength ranges for a given fluorophore. The sensitivity of the technique, when compared to absorption, arises from the fact that emission is a measure of low light levels above a theoretically zero background. In contrast, absorbance involves a measurement of the ratio of two large signals. The latter is a more difficult measurement. Therefore, the detection limit is typically 100 to 1000 times better in fluorimetry. These attributes make fluorescence spectroscopy a powerful tool for analytical measurements.

This text discusses fundamental principles involved in absorption and luminescence spectroscopies. Subsequent articles discuss specific topics and techniques in further detail (see Phosphorescence Measurements, Applications of Fluorescence Imaging Microscopy, Surface Measurements using Absorption/Luminescence). Articles Absorption and Luminescence Probes, Fluorescence in Organized Assemblies, and Indirect Detection Methods in Capillary Electrophoresis discuss other techniques in detail.
blue tinge in water stored in wood from the tree “lignum nephriticum”. The phenomenon of fluorescence was also described by Isaac Newton and documented by Robert Boyle\(^1\) in 1680. Throughout the 18th century, many new fluorescent materials were discovered, but an explanation of the phenomenon was not offered until 1833 when David Brewster\(^2\) attempted to explain the red fluorescence observed from a material extracted from green leaves. Brewster mistakenly ascribed the effect to light scattering, rather than an emission process.

The next report of the fluorescence phenomenon was in 1845 by the astronomer John Herschel,\(^3\) who examined the spectral properties of quinine solutions. Herschel noted that under certain observation angles, a “celestial blue colour” could be observed, although the solution appeared colorless under ordinary conditions. He noted the source of the blue emission was a well-defined area near the point of illumination and that even though the light was apparently transmitted through the solution, it lost the ability to produce the effect any further. He attributed the phenomenon to dispersion at the surface of the liquid and called the process epipolic. He referred to a beam of light that had passed through this solution as epipolized and considered it to be of a fundamentally different nature. In 1848, Brewster made note of Herschel’s report and was able to show that, under appropriate conditions, the blue light could be produced at a considerable distance from the surface of the solution.\(^4\) He contended that the observed phenomenon was simply a special case of internal dispersion. Both Herschel and Brewster noted that the light was qualitatively different after passing through the quinine solution, but could not explain the phenomenon and did not notice that the emitted light was of a longer wavelength. It is interesting and relevant to note that the concepts of absorption and emission had not yet been established.

In 1852, George Gabriel Stokes\(^4\) published a comprehensive paper of monumental importance in the field of fluorescence spectroscopy. In this paper, Stokes offered an alternative explanation to that of Brewster and Herschel. Using a solution of quinine, a small amount of sunlight was allowed to pass through a pinhole in a paper shield around the tube. The solution was observed from above and the blue fluorescence could be seen extending a short distance from the pinhole. Remarkably, Stokes was able to carry out a crude excitation scan, by observing the emission when the solution was placed in different parts of spectrally dispersed sunlight which had been passed through a prism. It was noted that the emission was most prominent when the solution was illuminated by light “a little short of the extreme violet” (note that quinine has a maximum excitation of \(\sim 350\) nm). These experiments showed that the “epipolized” light was not fundamentally different from the ordinary light, but simply lacked the shorter-wavelength components due to the filtering effect of the quinine absorption. Additionally, Stokes was able to show that the fluorescence emission was always of a longer wavelength than the absorption, a phenomenon we now refer to as the “Stokes shift”. Furthermore, it was in this paper that Stokes presented the term fluorescence, named after the fluorescent mineral fluorspar.

Later work by Stokes established the link between the concentration of a fluorescent solution and the intensity of its fluorescence, as well as the quenching which is observed at high concentrations due to the inner filter effect.\(^5\) Stokes is documented as being the first to suggest the analytical use of fluorescence, but Goppelsröder\(^6\) performed the first fluorimetric analysis in 1867, in which determination of the morin chelate of Al(III) was demonstrated. Table 1 provides a brief chronology of the discovery of luminescence.

## 2 ABSORPTION OF LIGHT

### 2.1 Interaction of Light and Matter

Molecular spectroscopy involves the interaction of light and matter. This includes such processes as reflection, refraction, scattering, and absorption. Although electromagnetic radiation can be considered as both a wave and a particle, many phenomena are adequately described by a classical treatment that considers the wave properties of electromagnetic radiation. Other phenomena, however, can only be explained by evoking theory that considers the particle properties of electromagnetic radiation (quantum mechanical model). In fact, much of the confusion and conflict surrounding early investigations of...
the fluorescence phenomenon (section 1.1) comes from the fact that classical wave theory could not adequately explain absorption and emission phenomena. It was not until nearly 30 years later with the discovery of the photoelectric effect that the particle properties of light could be used to describe absorption and emission processes. In this discussion, both theories will be used as necessary to convey concepts in the most efficient manner.

The wave model explains phenomena that do not involve absorption, e.g. diffraction, reflection, and refraction. The wave model depicts electromagnetic radiation as the propagation of mutually orthogonal magnetic and electric vectors, which oscillate at a characteristic frequency ($\nu$) and wavelength ($\lambda$). These two parameters are related by $\lambda \nu = c$, where $c$ is the speed of light in vacuum. A classical description of the interaction of light and matter can be considered as oscillations of the electrons and atoms that are induced by the interaction with the propagating wave. To explain absorption, quantum theory, which considers electromagnetic radiation as discrete packets of energy (photons), must be invoked. The energy of a photon is quantized, i.e. the energy of a particular photon is well defined. In addition, molecules are considered to exist in well-defined energy states. Since both absorption and emission processes are quantized, a transition can only occur when both the photon and the molecule are of a very specific energy. The energy ($E$) of a photon is related to its frequency ($\nu$) by Planck’s constant ($h$) as defined in Equation (1):

$$E = h\nu$$  \hfill (1)

Absorption of light by a molecule involves a transition of the molecule to a higher energy level. The energy of the absorbed photon is indicative of the energy difference between the two energy states, i.e. the ground state and the excited state. Therefore, absorption will only occur if the energy of the photon matches the energy difference between the two energy levels, as shown in Equation (2):

$$h\nu = E_2 - E_1$$ \hfill (2)

where $E_1$ and $E_2$ are the energies of the two energy states involved in the transition. The simplified energy-level diagram shown in Figure 1 illustrates this dependence.

Molecular changes that occur upon absorption can vary, depending on the magnitude of the energy. Upon absorption, the molecule is elevated to a higher energy level and this process is referred to as a molecular transition. Most molecules eliminate this excess energy through heat dissipation with its surroundings. Under certain conditions, the reverse of absorption can occur, whereby a molecule emits a photon as it returns to a lower energy state. This emission process is governed by the same selection rules as absorption and is a quantized phenomenon.

2.2 Principle Modes of Absorption

A simple example of absorption is atomic absorption. In this case, the energy level of the atom is determined by the arrangement of electrons around the nucleus. Absorption signifies movement to a higher energy level through promotion of an electron to a higher orbital. Atomic emission is the opposite process, whereby the energy of the atom is lowered by the emission of a photon, the energy of which corresponds to the energy gap between the two atomic orbitals. In the case of molecular absorption, however, one must consider other forms of energy in addition to the electronic energy. Unlike atoms, molecules can undergo transitions to elevated energy levels through different vibrational and rotational modes.

The type of transition involved is dependent on the energy of the photon. Absorption of light in the ultraviolet and visible regions typically involves electronic transitions of the outer electrons. Absorption in the infrared region involves transitions to higher vibrational levels, while the far-infrared and microwave regions consist of rotational transitions. Absorption in the ultraviolet/visible (UV/VIS) region can involve one or more of these transitions. The total energy ($E_{\text{tot}}$) of the molecule is then the sum of the electronic ($E_{\text{elec}}$), vibrational ($E_{\text{vib}}$), and rotational ($E_{\text{rot}}$) energies, as shown in Equation (3):

$$E_{\text{tot}} = E_{\text{elec}} + E_{\text{vib}} + E_{\text{rot}}$$ \hfill (3)

The various electronic, vibrational, and rotational energy levels are illustrated in the energy level diagram shown in Figure 2.

The energy of the excited-state transition is the change in the total energy of the molecule and corresponds to the energy of the photon involved in the transition, as shown
in Equation (4).

\[ \Delta E_{tot} = h\nu = \frac{hc}{\lambda} \]  

(4)

The vertical transition shown in Figure 2 involves electronic, vibrational, and rotational transitions, as respectively indicated by the \( S_0 \rightarrow S_1, \nu_0 \rightarrow \nu_1 \) and \( J_1 \rightarrow J_3 \) transitions. An absorption spectrum is a measure of the absorbance as a function of wavelength. In the theoretical case of an isolated molecule and a perfect spectrometer, a line of finite width would be measured for each electronic, vibrational, and electronic transition. Atomic absorption spectra and some vapor-phase molecular absorption spectra come close to this prediction, with the limiting factor often being the resolving power of the spectrometer. A classic example of such a molecular absorption spectrum is that obtained for iodine vapor. It should be noted that an important aspect of an absorption spectrum is that the relative intensities of each line are indicative of the probability of a given transition, although instrumental artifacts can affect this.

Even though each transition is quantized, absorption spectra do not always show discrete rotational, vibrational, and electronic energy levels. Often, the interval between rotational and vibrational energy levels can be rather small. Moreover, in a sample containing many molecules, the energy level of each molecule can vary slightly due to localized variations, resulting in overlapping energy transitions. This effect is compounded in solution phase, resulting in relatively broad absorption bands. The degree of vibrational structure evident in the measured spectrum is a function of the solvent and structure of the molecule. Some rigid molecules, such as polyaromatic hydrocarbons, show vibrational structure. Most condensed-phase absorption spectra are, however, very broad and featureless.

Finally, it should be noted that the Beer–Lambert law describes the absorbance of a molecule, as shown in Equation (5)

\[ A = \varepsilon bc \]  

(5)

where \( \varepsilon \) is the molar extinction (probability of absorption), \( b \) is the cell pathlength and \( c \) is the molar concentration of absorber in the cell. It should be noted from Equation (6) that

\[ A = \log \frac{I_o}{I_t} \]  

(6)

where \( I_o \) is the intensity of the incident light and \( I_t \) is the intensity of the transmitted light. Rearranging this equation gives Equation (7):

\[ A = \log I_o - \log I_t \]  

(7)

Therefore, absorbance is a measure of the difference in the logarithm of the intensities and not the difference in intensities as one might intuitively expect. This is because absorption is an exponential function of cell pathlength and concentration of absorber.

A more thorough treatment of absorption spectrometry and associated techniques can be found in other articles within this section. (See Near-infrared Absorption/Luminescence Measurements, Circular Dichroism and Linear Dichroism).

3 LUMINESCENCE PRINCIPLES

3.1 Multiplicity

The multiplicity is defined as shown in Equation (8)

\[ M = 2(S) + 1 \]  

(8)
where \( M \) is the multiplicity and \( S \) is the spin quantum number of the molecule. Thus, the multiplicity is simply a representation of the number of unpaired electrons in the molecular orbital of the molecule. We shall restrict our discussion to the most common fluorescent molecules, i.e. organic molecules, which typically have an even number of electrons. Of course, free radicals are an exception. For an even number of electrons, \( S = 0 \) and the multiplicity is given by Equation (9):

\[
M = 2(0) + 1 = 1
\]  

(9)

and the molecule exists as a singlet state, i.e. \( M = 1 \). Therefore, the ground state in most organic molecules exists as a singlet energy state. It is possible, however, for the spin of an electron in an excited state to become reversed, resulting in two unpaired electrons. In this case, the spin is equal to 1 and the multiplicity is given by Equation (10):

\[
M = 2(1) + 1 = 3
\]  

(10)

This state is referred to as a triplet state (T). The multiplicities of the energy states involved in a luminescence transition are of great importance, as they designate the fundamental difference between fluorescence and phosphorescence, as noted in section 1.

### 3.2 Photoluminescence Transitions

Fluorescence is by far the most commonly employed luminescence technique and as such, it will be covered in greater detail. Fluorescence is a competitive process based on the formation of excited-state molecules and subsequent deactivation to a lower energy state. Molecular and environmental parameters affect the kinetics of this process. In fact, some of the most useful luminescence techniques are based on this dependence. Jablonski\(^7\) first suggested explaining luminescence by use of the energy level diagram shown in Figure 3.

This diagram is an effective method of visualizing the different transitions involved in the processes of luminescence. The ground, first, and second excited states are depicted as \( S_0 \), \( S_1 \) and \( S_2 \), indicating singlet states of different energies. The term \( T_1 \) designates the triplet state. Within each electronic energy level, vibrational and rotational energy levels are designated as \( \nu_n \) and \( J_n \), respectively. Figure 3 is separated into three parts illustrating the absorption, fluorescence, and phosphorescence phenomena. Vertical transitions denote transitions that occur on a very rapid timescale and can be considered as virtually instantaneous. Nonvertical lines are used to depict transitions occurring on a timescale slower than that of the vertical transitions. When a photon of an appropriate wavelength is absorbed by a molecule, the molecule is excited to a higher energy state. At room temperature, the vast majority of molecules will reside in the lowest vibrational level of the ground electronic state, i.e. the \( S_0 \) state for organic molecules. This is illustrated by considering the Boltzmann distribution, which is given by Equation (11)

\[
R = e^{-\Delta E/kT}
\]  

(11)

where \( R \) is the ratio of molecules in a given state, \( \Delta E \) is the energy difference between the two states, \( k \) is the Boltzmann constant and \( T \) is the temperature in Kelvin. Consider the distribution of molecules between the \( S_0\nu_0 \) and \( S_0\nu_1 \) states. Using a typical vibrational energy gap of

---

**Figure 3** Jablonski energy level diagram illustrating photoluminescence processes.
1500 cm\(^{-1}\) and a temperature of 300 K, only 1% of the molecules will reside in the \(S_0v_1\) state. The population of other excited states, such as higher electronic states, will be even smaller than this since \(\Delta E\) is significantly greater. It should therefore be apparent that absorption will almost always involve excitation of a molecule from the lowest vibrational level of the ground state.

Upon absorption of photon energy, a molecule will act to minimize this energy by undergoing one of several transitions. The first and most rapid transition involves relaxation of the molecule to the lowest vibrational state of \(S_1\). This is typically true, whether the absorption involved is to \(S_1\) or \(S_2\). This rapid relaxation process is referred to as internal conversion. From the lowest vibrational state of \(S_1\), the excited molecule can further lower its energy by emission of a photon (fluorescence emission) or by conversion to the triplet state, \(T_1\). The latter process is referred to as intersystem crossing and is a much slower process than internal conversion, since the multiplicity of the molecule must change during the transition. Processes that involve changes in multiplicity are termed “forbidden processes”, i.e. have a low probability of occurring.

Once in the triplet state, the molecule can then lower its energy further by emission of a photon (phosphorescence). Note that the transition from \(T_1\) to \(S_0\) involves states of different multiplicities and is therefore a forbidden transition, occurring only under certain conditions, with low efficiency and at a slow rate. It should also be noted that since \(T_1\) is lower in energy than \(S_1\), phosphorescence occurs at longer wavelengths and is a much slower process with phosphorescence lifetimes ranging from microseconds to several seconds. This can be compared to fluorescence lifetimes, which are typically in the nanosecond range.

3.3 **Stokes' Law**

Internal conversion from excited states higher than \(S_1\) typically occurs within \(10^{-12}\) s. Since most fluorescence lifetimes are in the order of \(10^{-9}\) s, this ensures that molecules will usually return to the lowest vibrational level of \(S_1\) prior to emission. The energy gap between \(S_1\) and \(S_0\) is significantly larger, such that fluorescence becomes competitive with internal conversion for many molecules.

As noted in section 3.1, absorption usually occurs from the lowest vibrational level of the ground state. Thus, the fluorescence process typically involves absorption from the lowest vibrational level of \(S_0\) and emission from the lowest vibrational level of \(S_1\). As a consequence, fluorescence emission always occurs at a wavelength equal to, or longer than, that of the absorption. In fact, with the exception of some gas-phase molecules, emission is always of a longer wavelength than the absorption due to energy losses from solvent interactions. This is commonly referred to as the Stokes shift and was first noted by Stokes in 1852\(^4\) (see section 1.1).

3.4 **Franck–Condon Principle and Mirror Imagery**

The absorption process is generally acknowledged to occur within one oscillation period of the absorbed light, which corresponds to a time period of \(1 \times 10^{-15}\) s for light in the ultraviolet region. The Franck–Condon principle assumes that the position and momentum of the molecule will not change during excitation. This means that the probability (Franck–Condon factor) of a transition is the same in the up (absorption) and down (emission) process. In other words, an intense band in the absorption spectrum will also be an intense band in the emission spectrum. A practical consequence of this is referred to as the mirror image rule (Figure 4).

There are many exceptions to the mirror image rule. These typically involve processes that affect the excited and ground states differently. For example, if the molecule becomes more rigid in the excited state, as is the case in the example of biphenyl shown in Figure 5, the emission may exhibit more defined vibrational structure than does the absorption spectrum.

3.5 **Kinetics of Fluorescence**

Fluorescence is a process controlled by a number of competing processes. For a given population of molecules in an excited state, not all will return to the ground state by a radiative process. The fraction of molecules in the excited state that do return to the ground state via fluorescence emission is referred to as the quantum yield efficiency, \(\Phi_f\). In its most fundamental representation, the

![Figure 4](image-url)
quantum yield is simply the ratio of quanta of light emitted to quanta of light absorbed (Table 2). The quantum yield is a parameter that is affected by molecular properties as well as the solvent and environment surrounding the molecule. It has also been shown that temperature as well as excitation wavelength can have a marked effect on the quantum efficiency.\(^8\)

Let us now consider the factors that affect fluorescence yield. The first of these is the process of absorption. The rate of formation of excited-state molecules by the absorption process is directly proportional to the molar absorptivity \((\varepsilon)\) of the molecule, the intensity of the incident light \((I_0)\), and the concentration of molecules in the ground state \([S_0]\). The intensity of the absorbed light \((I_a)\) is given by Equation (12):

\[
I_a = I_0 - I_t \tag{12}
\]

where \(I_t\) is the intensity of the transmitted light and can be considered the rate of absorption. If the sample is excited for a period of time that is long, compared to the rates of deactivation processes, the number of molecules in the excited state \([S_1]\) will reach a steady state. The activation (absorption) rate will then be dependent on the rate of the deactivation processes, as this determines the population of molecules in the ground state. Therefore, under steady-state illumination the rate of absorption \((\Gamma_a)\) is related to the rate of deactivation, i.e. the rate constants of the deactivation pathways, as shown in Equation (13):

\[
\Gamma_a = (k_{vt} + k_{ic} + k_{isc} + k_t + k_0[Q])[S_1] \tag{13}
\]
where $k_{\text{vr}}$, $k_{\text{ic}}$, $k_{\text{isc}}$, $k_t$, and $k_Q$ are the rate constants for vibrational relaxation, internal conversion, intersystem crossing, fluorescence, and quenching, respectively. The term $[S_1]$ is the concentration of species that occupy the $S_1$ energy state under steady-state conditions and $[Q]$ is the concentration of quencher molecules. These rate constants and the processes they represent are summarized in Table 3.

As previously mentioned, the quantum efficiency ($\Phi_t$) is the fraction of absorbed photons that result in photon emission. The rate of fluorescence is therefore proportional to the rate of absorption as shown by Equation (14):

$$\Gamma_t = \Phi_t I_A$$

and Equation (15) gives:

$$\Gamma_t = k_t[S_1] = (k_{\text{vr}} + k_{\text{ic}} + k_{\text{isc}} + k_t + k_Q[Q])[S_1] \Phi_t$$

The fluorescence quantum efficiency is then given by Equation (16):

$$\Phi_t = \frac{k_t}{k_t + k_d}$$

where $k_t$ is the rate of deactivation via fluorescence and $k_d$ is the rate constant for all other deactivation processes. The rate constant $k_d$ represents internal conversion ($k_{\text{ic}}$), vibrational relaxation ($k_{\text{vr}}$), intersystem crossing ($k_{\text{isc}}$), and collisional quenching ($k_Q$).

### 3.6 Linearity of Fluorescence

Much of the utility of fluorescence spectroscopy comes from the linearity of the fluorescence intensity as a function of concentration. This linearity can often extend over a relatively broad concentration range, especially for fluorophores with high quantum efficiencies. It is useful to consider the factors that affect the intensity of a fluorescent sample. As mentioned previously, under steady-state illumination the intensity of the fluorescence signal is equal to the rate of light absorption multiplied by the quantum efficiency, as shown in Equation (17):

$$I_t = \Gamma_t \Phi_t = (I_o - I_d) \Phi_t$$

From the Beer–Lambert law, the absorbed light can be related to the molar absorptivity ($\varepsilon$), cell pathlength ($b$), and concentration ($c$) as shown in Equation (18):

$$\frac{I_o}{I_o} = e^{-ebc}$$

Substitution of Equation (18) into Equation (17) results in Equation (19):

$$I_t = I_o(1 - e^{ebc}) \Phi_t$$

A Taylor expansion can then be used to expand the exponential portion of Equation (18), resulting in Equation (20):

$$I_t = I_o \left(1 - \frac{ebc}{2} + \frac{ebc^2}{6} - \cdots \right) \Phi_t$$

When the absorbance of the solution is low ($\leq 0.01$), Equation (19) can be reduced to Equation (21):

$$I_t = \Phi_t I_o e^{ebc}$$

This shows that the rate of fluorescence is directly proportional to the quantum efficiency ($\Phi$), the intensity of the exciting radiation ($I_o$), the molar absorptivity ($\varepsilon$), the pathlength ($b$), and the concentration of the fluorophore ($c$). Given that the quantum efficiency, molar absorptivity, intensity of the incident beam, and the pathlength will all be constant during a given experiment, the intensity of the fluorescence signal is then directly related to the concentration of the fluorophore by Equation (22):

$$I_t = kc$$

where $k$ is a constant for a given experiment.

### 3.7 Fluorescence Lifetime

The fluorescence lifetime is another characteristic parameter of a fluorophore in a given environment. This parameter represents the probability of finding a molecule in the excited state at a given time. This fundamental parameter can be derived by letting $n_0$ represent the number of molecules in the ground state. We will also assume that fluorescence emission is the only path for the excited molecule to return to the ground state. Therefore, at time $t$, the number of molecules emitting per second is
proportional to \( n_e \), the number of molecules in the excited state. This can be written as shown in Equation (23):

\[
\frac{dn}{dt} = -k_i n_t
\]

where \( k_i \) is the fluorescence rate constant. Integrating Equation (23) gives Equation (24):

\[
\frac{dn}{n_t} = -k_i dt
\]

The resulting dependence of the excited-state population on time is shown in Equation (25).

\[
n = n_0 e^{-k_i t}
\]

This equation represents the average time that a molecule will reside in the excited state.

The intrinsic fluorescence lifetime (\( \tau_0 \)) is defined as the time required for all but 1/e of the excited state molecules to return to the ground state. This does not specify the path of relaxation to the ground state and encompasses all relaxation processes, both radiative and nonradiative. The radiative, or observed, lifetime (\( \tau \)) refers specifically to the decay in fluorescence intensity following the cessation of steady-state illumination and is given by Equation (26):

\[
I = I_0 e^{-t/\tau}
\]

where \( I \) is the fluorescence intensity, \( I_0 \) is the fluorescence intensity at \( t = 0 \) and \( \tau \) is the observed fluorescence lifetime. In the absence of any nonradiative relaxation mechanisms, the fluorescence lifetime and the fluorescence rate constant are related by Equation (27):

\[
\tau = \frac{1}{k_i}
\]

From this expression, the quantum yield can be expressed in terms of the intrinsic and observed lifetime as shown in Equation (28)

\[
\Phi_t = \frac{\tau}{\tau_0}
\]

making it possible to determine one unknown quantity, if the other two are known.

It is worthwhile to note that the spontaneous emission of light is proportional to the molar absorptivity. This is due to the fact that, in most cases, the excited molecule will reach thermal equilibrium prior to emission and the transition probabilities will be similar for both the emission and absorption processes. Therefore, there is an empirical link between absorptivity and the lifetime of a given fluorophore. An estimation of the radiative lifetime can be obtained using Equation (29)

\[
\frac{1}{\tau_0} = \varepsilon_{\text{max}} \times 10^4
\]

where \( \varepsilon_{\text{max}} \) represents the maximum value of the extinction coefficient of the major absorption band. Although this relationship is dependent on many assumptions, it is a useful way of emphasizing the dependence of the intrinsic lifetime on the molar absorptivity. It should be noted that lifetimes estimated in this fashion are only valid for the intrinsic lifetime. If any nonradiative relaxation mechanisms are present, significant errors will occur and the observed lifetime will be shorter than the calculated lifetime. There are more rigorous methods of estimating the lifetime, but the intent of the current discussion is to simply note the dependence of the fluorescence lifetime on the molar absorptivity.

Recalling that the fluorescence and nonradiative rate constants are \( k_i \) and \( k_d \), respectively, the fluorescence lifetime, \( \tau \), can be given by Equation (30):

\[
\frac{1}{\tau} = k_i + k_d
\]

A straightforward conclusion of the above relationship is that both processes determine the lifetime only when they are both of the same order of magnitude. If one process is much faster than the other, the relaxation rate will solely be determined by the faster process.

Fortunately, the decay time does not depend on the concentration of the fluorophore. This parameter can then be used by the experimentalist to examine situations under which the concentration of the fluorophore cannot be held constant, such as in the case of photobleaching. This scenario makes steady-state fluorescence measurements unreliable for quantitative studies. In such cases, the fluorescence decay time provides a more reliable measure of the fluorescence properties.

3.8 Fluorescence Quenching

Fluorescence quenching is one of the more analytically useful processes that compete with the fluorescence process. Thus many analytical techniques have been developed on the basis of fluorescence quenching. In the most general sense of the term, fluorescence quenching refers to any process that leads to a reduction in the fluorescence intensity of a given system. A more rigorous definition states that the reduction in intensity must involve nonradiative deactivation from the excited state. Based on these definitions, there are two basic categories of fluorescence quenching. The first is dynamic quenching, which involves nonradiative deactivation of the excited state upon collision with another molecule. The second is referred to as static quenching and refers to
a phenomenon where complex formation in the ground state precludes the formation of an excited-state species. While both types of quenching lead to a decrease in the observed fluorescence intensity, they are fundamentally different and thus will be discussed separately.

3.8.1 Dynamic Quenching

Dynamic quenching occurs when a molecule collides with the fluorophore during the lifetime of the excited state. As a result of the collision, the fluorophore relaxes to the ground state. This causes a decrease in the fluorescence lifetime of the species as well as a decrease in the fluorescence intensity. In the absence of quenching, the fluorescence quantum efficiency, $\Phi_o$, is given by Equation (31).

$$\Phi_o = \frac{k_i}{k_{ic} + k_{isc} + k_i}$$  (31)

When quenching processes are present, the quenching rate and the concentration of quencher must be included, as shown in Equation (32).

$$\Phi = \frac{k_i}{k_{ic} + k_{isc} + k_i + k_Q[Q]}$$  (32)

Combining Equations (31) and (32), the ratio of the quantum efficiency in the absence and presence of quencher is given by Equation (33).

$$\frac{\Phi_o}{\Phi} = 1 + \frac{k_Q[Q]}{k_{ic} + k_{isc} + k_i} = 1 + \tau_0 k_Q[Q]$$  (33)

Alternatively, Equation (33) can be used to express the fluorescence efficiency in terms of fluorescence lifetime:

$$\frac{\tau_0}{\tau} = 1 + \tau_0 k_Q[Q] = 1 + K_{SV}[Q]$$  (34)

where $\tau_0$ and $\tau$ are the fluorescence lifetimes in the absence and presence of quencher and $K_{SV}$ is the Stern–Volmer quenching constant. Equations (33) and (34) were first used by Stern and Volmer in 1919 and the Stern–Volmer equation is usually used in the form given in Equation (35):

$$\frac{F_0}{F} = K_{SV}[Q] + 1$$  (35)

Equation (35) shows that a linear relationship exists between the ratio of the fluorescence intensity in the presence and absence of quencher ($F_0/F$) and the concentration of quencher. Therefore, a plot of the ratio $F_0/F$ as a function of $[Q]$ will yield a linear plot, the slope of which is equal to the Stern–Volmer constant. A typical Stern–Volmer plot is illustrated in Figure 6.

3.8.2 Static Quenching

Static quenching is a process that leads to a reduction in the observed fluorescence intensities, but not the quantum yield of fluorescence. Thus, the fundamental difference between dynamic and static quenching is that the quantum efficiency is not affected in static quenching. This is because static quenching leads to reduced fluorescence intensities by the formation of a ground-state complex. This ground-state complex precludes radiative deactivation to the ground state. The equilibrium of the complex can be given by Equation (36):

$$F + Q \rightleftharpoons F-Q$$  (36)

where $F$ is the fluorescent species, $Q$ is the quencher and $F-Q$ is the complex. The equilibrium for this complex formation is given by Equation (37):

$$K_{eq} = \frac{[F-Q]}{[F][Q]}$$  (37)

where $[F-Q]$ is the concentration of the complex. In the case where the complex is nonfluorescent, a useful relation can be developed. Let $[F_o]$ be the total concentration of fluorophore. The total fluorophore concentration is given by Equation (38):

$$[F_o] = [F] + [F-Q]$$  (38)

Substitution of Equation (38) into Equation (37) results in Equation (39):

$$K_{eq} = \frac{[F_o] - [F]}{[F][Q]} = \frac{[F_o]}{[F][Q]} - \frac{1}{[Q]}$$  (39)
which, upon rearrangement has the same form as the Stern–Volmer equation, as shown in Equation (40):

\[
\frac{F_0}{F} = K_{eq}[Q] + 1 \quad (40)
\]

However, in this form, the Stern–Volmer constant is replaced with \( K_{eq} \), the equilibrium constant for the formation of the complex. This equation can be used to produce a plot analogous to that shown in Figure 6. This equation has led to the use of static quenching for the determination of formation constants.

In many experiments, it is important to determine whether the observed quenching is the result of dynamic or static quenching. There are several methods that can be used to distinguish between these two mechanisms of quenching. These methods are based on fundamental differences between dynamic and static quenching. The most conclusive method is to construct a Stern–Volmer plot using fluorescence lifetimes, rather than intensities. Since static quenching involves the formation of a ground-state complex which precludes emission from the excited state, no fluorescence is observed from the complexed fluorophore and the uncomplexed species are not affected. Thus, even though the intensities may change as a function of quencher concentration, the fluorescence lifetime will not. Hence, the Stern–Volmer plot will have a slope of zero in the case of static quenching. This is illustrated in Figure 7.

Another method that may be used to determine the form of quenching is to examine the temperature dependence of the quenching. With increased temperature, Brownian motion results in a higher rate of collisional encounters. This will have different effects on dynamic quenching and static quenching. In the case of dynamic quenching, increased collisional encounters lead to increased quenching. In the case of static quenching, the opposite effect is usually observed, since the stability of the complex will often decrease at higher temperatures. These effects are depicted in Figure 8.

Figure 7 Idealized Stern–Volmer plots for dynamic and static quenching measured in terms of fluorescence lifetime.

Figure 8 Change in Stern–Volmer plots for static (a) and dynamic (b) quenching in response to increased temperature (· · · ·).

3.9 Polarization

Fluorescence anisotropy is a technique that can elucidate the rotational motion of a fluorophore by measuring the polarization of the fluorescence emission. This technique can be utilized for analytical measurement in several ways, particularly since the size and shape of the fluorophore, the viscosity and temperature of the solvent environment, as well as binding interactions all influence the rotational diffusion of a molecule. This has led to the use of fluorescence anisotropy as a tool in the study of binding interactions, microviscosities of membranes and micelles, and conformational changes in DNA, just to name a few. Most recently, fluorescence anisotropy has been used as a novel visual sensing device likely to find use in bioanalytical sensing applications.

When a fluorophore is excited with plane-polarized light, the subsequent emission from that molecule will be partially polarized. The degree of polarization depends on both intrinsic (molecular) and extrinsic (environmental) parameters. This dependence has led to the use of polarized fluorescence in the study of micellar and other microheterogeneous systems. Experimentally, the sample is excited with a plane-polarized beam of light, usually with vertical polarization. The intensity of the fluorescence emission is then measured after transmission of the light through a polarizer, which permits passage of vertically polarized light. This allows measurement of the parallel component (parallel to the exciting light) of the emission. The polarizer is then rotated 90° in order to
collect the perpendicular emission component. Together, these two measurements are used to represent the degree of polarization of the fluorescence emission.

The degree of polarization of light emitted from a fluorescent molecule can be described as either the fluorescence polarization \( P \), or the fluorescence anisotropy \( r \). These parameters are defined in Equations (41) and (42) respectively:

\[
P = \frac{I_\parallel - I_\perp}{I_\parallel + I_\perp} \quad \text{(41)}
\]

\[
r = \frac{I_\parallel - I_\perp}{I_\parallel + 2I_\perp} \quad \text{(42)}
\]

where \( I_\parallel \) and \( I_\perp \) are the fluorescence emission intensities measured with polarization parallel and perpendicular to the polarization of the excitation radiation. For completely polarized light, both the polarization and anisotropy are equal to 1.0, and for nonpolarized light the anisotropy and polarization are equal to 0.0. At intermediate degrees of polarization, however, the anisotropy and polarization are not equal. As was first noted by Jablonski, \( ^{20} \) most theoretical expressions are much simpler when expressed in terms of anisotropy. A prime example of this is illustrated by considering the polarization measured from a mixture of fluorophores. The polarization of a mixture of fluorophores is given by Equation (43):

\[
\frac{1}{P_{\text{avg}}^{-1}} = \sum_i f_i \left( \frac{1}{P_i^2} - \frac{1}{3} \right) \quad \text{(43)}
\]

where \( P_{\text{avg}} \) is the average polarization of the mixture, \( P_i \) is the polarization of component \( i \), and \( f \) is the fractional contribution of the component to the overall intensity. This can be contrasted with the much simpler expression (Equation 44) obtained when the polarization is expressed as an anisotropy value.

\[
r_{\text{avg}} = \sum_i f_i r_i \quad \text{(44)}
\]

Similar simplification is found in most other expressions. The most significant observation is that the time-dependent anisotropy decays as a single exponential for spherical molecules, as shown in Equation (45):

\[
r(t) = r_0 e^{-t/\phi} \quad \text{(45)}
\]

where \( r_0 \) is the anisotropy at \( t = 0 \), and \( \phi \) is the rotational correlation time for the molecule. Equation (45) will be discussed later in further detail.

For the reasons identified above, anisotropy will be used in this discussion, although polarization values are often encountered in the older literature. Importantly, the relations shown in Equations (46) and (47) can convert either value.

\[
P = \frac{3r}{2 + r} \quad \text{(46)}
\]

\[
r = \frac{2P}{3 - P} \quad \text{(47)}
\]

At this point, it is necessary to define a set of general coordinates which defines the discussion presented here. Fluorescence measurements are typically performed with an observation angle of 90°, and this configuration will be assumed throughout this discussion. With this configuration, the three primary instrumental components define the \( x,o,y \)-plane, where \( x \) is the direction of observation, \( o \) is the origin, or center of the irradiated volume, and \( y \) is the direction of the excitation beam (Figure 9).

These coordinates are used to define the molecular orientation and the polarization components of the excitation and emission with a common frame of reference. The fluorescence intensity measured at these coordinates is given by \( I_x \), \( I_y \), and \( I_z \) and the total fluorescence intensity, \( S \), is given by Equation (48):

\[
S = I_x + I_y + I_z \quad \text{(48)}
\]

Equation (49) shows that when the excitation beam is vertically polarized along the \( z \)-axis,

\[
I_x = I_y \quad \text{(49)}
\]

and Equation (50) gives

\[
S = I_z + 2I_x \quad \text{(50)}
\]

Equation (51) shows that if the excitation beam is horizontally polarized along the \( x \)-axis, then

\[
I_y = I_z \quad \text{(51)}
\]

\[\text{Figure 9} \quad \text{Operational coordinates used in fluorescence polarization studies.}\]
and Equation (52) gives

\[ S = 2I_t + I_v \]  \hspace{1cm} (52)

Therefore, if the sample is excited with vertically polarized radiation, the emission component oriented along the \( z \)-axis corresponds to the parallel component \( (I_p) \) and that in the direction of the \( y \)-axis corresponds to the perpendicular component \( (I_v) \). In order to selectively measure these two components of the emission, a polarizing device is placed in the optical path of the fluorescent emission. In this scenario, the emission intensity measured with the emission polarizer in a vertical position corresponds to the parallel component and is denoted by Equation (53)

\[ I_{vv} = I_p \] \hspace{1cm} (53)

where the “v,v” subscript denotes the vertical orientation of the excitation and emission polarizers. Measurement of the perpendicular component is denoted in a similar manner as shown in Equation (54)

\[ I_{vh} = I_v \] \hspace{1cm} (54)

The fluorescence anisotropy is defined by Equation (55)

\[ r = \frac{I_p - I_v}{S} \] \hspace{1cm} (55)

which is sometimes represented by Equation (56)

\[ r = \frac{D}{S} \] \hspace{1cm} (56)

where \( D \) simply denotes the difference between the parallel and perpendicular components of the emission. Most often, the fluorescence anisotropy is denoted by Equation (57)

\[ r = \frac{I_p - I_v}{I_v + 2I_{vh}} \] \hspace{1cm} (57)

illustrating that, fundamentally, two measurements must be made in order to determine the fluorescence anisotropy.

**G-factor.** In most cases, a correction called the \( G \)-factor must be made to anisotropy measurements. This is due to the fact that most fluorimeters and optics are biased toward a particular polarization of light. Additionally, even though the light source may produce unpolarized light, some instrumental components (e.g. gratings) will impart some degree of polarization. The \( G \)-factor is simply a measure of the polarization bias of the instrument. This is typically determined by changing the excitation polarizer to a horizontal position. In this position, both horizontal and vertical polarizer positions are perpendicular to the polarization of the excitation beam. Therefore, any differences in the fluorescence intensity are due to instrumental artifacts. The \( G \)-factor is given by Equation (58)

\[ G = \frac{I_{vh}}{I_{hh}} \] \hspace{1cm} (58)

and the corrected anisotropy is calculated using Equation (59).

\[ r = \frac{I_p - I_v G}{I_p + 2I_{vh} G} = \frac{I_{vv} - I_{vh} G}{I_{vv} + 2I_{vh} G} \] \hspace{1cm} (59)

### 3.9.1 Photoselection

A fundamental and critical aspect of the absorption of polarized light is the fact that only those molecules of a well-defined orientation will be excited. This is referred to as photoselection and is of utmost importance to understand fluorescence anisotropy. Recall that light consists of mutually orthogonal waves of electric and magnetic vectors propagating in the direction of the light path. Natural light that is unpolarized consists of photons whose electric field vectors are randomly oriented. When unpolarized light is passed through a polarizing element, only those photons with electric field vectors of one orientation are permitted to pass. Note that it is predominantly the oscillation of the electric field that has the greatest interaction with matter. Hence, when light is referred to as being vertically polarized, the orientation refers to the electric field vector. Absorption is greatest when the oscillation of the electric field is collinear with the orientation of the absorption dipole of the molecule. Therefore, those molecules which are properly aligned, relative to the polarization of the incident radiation, will preferentially absorb radiation and subsequently fluoresce. In other words, when the excitation is produced with polarized radiation, fluorescence emission results from those molecules which are “photoselected” during the excitation process.

### 3.9.2 Depolarization

#### 3.9.2.1 Intrinsic Depolarization

There are several mechanisms that lead to depolarization. These can be classified as intrinsic (molecular) and extrinsic (environmental) mechanisms. The two intrinsic mechanisms are photoselection and the angular separation between the excitation and emission dipoles. The major extrinsic form of depolarization is molecular rotation.

In dilute vitrified solutions, the extrinsic depolarization mechanisms (rotation and energy transfer) have been removed and any depolarization observed is due to intrinsic phenomena. Since fluorescence emission is only observed from molecules that have been “photoselected”,

\[ I_{vh} \] refers to the electric field vector. Absorption is greatest when the oscillation of the electric field is collinear with the orientation of the absorption dipole of the molecule. Therefore, those molecules which are properly aligned, relative to the polarization of the incident radiation, will preferentially absorb radiation and subsequently fluoresce. In other words, when the excitation is produced with polarized radiation, fluorescence emission results from those molecules which are “photoselected” during the excitation process.

#### 3.9.2.2 Intrinsic Depolarization

There are several mechanisms that lead to depolarization. These can be classified as intrinsic (molecular) and extrinsic (environmental) mechanisms. The two intrinsic mechanisms are photoselection and the angular separation between the excitation and emission dipoles. The major extrinsic form of depolarization is molecular rotation.

In dilute vitrified solutions, the extrinsic depolarization mechanisms (rotation and energy transfer) have been removed and any depolarization observed is due to intrinsic phenomena. Since fluorescence emission is only observed from molecules that have been “photoselected”,

\[ I_{vh} \] refers to the electric field vector. Absorption is greatest when the oscillation of the electric field is collinear with the orientation of the absorption dipole of the molecule. Therefore, those molecules which are properly aligned, relative to the polarization of the incident radiation, will preferentially absorb radiation and subsequently fluoresce. In other words, when the excitation is produced with polarized radiation, fluorescence emission results from those molecules which are “photoselected” during the excitation process.
one would expect the polarization to be preserved through the emission process, as in the case of light scattering. This is not observed, however, since the molecules need not be perfectly aligned in order to absorb radiation. A range of orientations is actually “photoselected” and this range is proportional to $\cos^2 \theta$, where $\theta$ is the angle between the absorption dipole and the polarization of the exciting radiation (z-axis), as shown in Figure 10.

As a result, a cone of molecules randomly distributed about the z-axis will be selected. Thus, even in the absence of molecular rotation, emission from some molecules will not have completely vertical polarization and the emission will have components of both parallel and perpendicular orientations. The distribution of molecules excited is then given by Equation (60).

$$f(\theta) \, d\theta = \cos^2 \theta \sin \theta \, d\theta$$

(60)

In the case of randomly distributed molecules that have collinear absorption and emission dipoles, the distribution suggested in Equation (60) can be reduced to Equation (61)

$$\cos^2 \theta = \frac{3}{5}$$

(61)

The dependence of the anisotropy on the orientation of the absorption dipole is then given by

$$r = \frac{3 \cos^2 \theta - 1}{2}$$

(62)

where $\theta$ is the angle between the emission dipole and the z-axis. From Equations (61) and (62) it can be shown that the maximum anisotropy that can be obtained in an isotropic solution of fluorophores is 0.4. This value is observed when the absorption and emission dipoles are collinear. This scenario is rarely encountered and very few molecules have absorption and emission dipoles that are nearly collinear. The angular displacement between the absorption and emission dipoles is referred to as the $\alpha$-angle and causes an additional decrease in the anisotropy.

Together, the $\alpha$-angle and the process of photoselection define the intrinsic anisotropy, $r_o$, which is the anisotropy that would be measured in the absence of molecular rotation. The dependence of the intrinsic anisotropy on these processes is given by Equation (63).

$$r_o = \frac{2}{5} \left( 3 \cos^2 \alpha - 1 \right)$$

(63)

### 3.9.2.2 Extrinsic Depolarization

Consider the case of a dilute isotropic solution of a fluorescent species. Once photoselection and excitation have occurred, the molecule will reside in the excited state for a period of time, prior to fluorescence emission. The amount of time that the molecule spends in the excited state is dependent on the fluorescence lifetime and the anisotropy will be reduced based on the degree of rotation that occurs during the excited state. From these considerations, it can be seen that there is a fundamental association between the measured anisotropy, the rotational rate of the molecule, and the fluorescence lifetime. These are related by the Perrin equation, as shown in Equation (64)

$$\frac{r_o}{r} = 1 + \frac{\tau}{\phi}$$

(64)

where $r_o$ is the intrinsic anisotropy, $r$ is the measured anisotropy, $\tau$ is the fluorescence lifetime and $\phi$ is the rotational correlation time of the molecule. By use of the Perrin equation, it is possible to determine the rotational diffusion rate of a molecule if the fluorescence lifetime and the intrinsic anisotropy are known. It is important to note that the measured rotational diffusion refers to that of the rotating species. In the case of simple fluorescent molecules, this corresponds to the rotation of the entire molecule. However, in the case of a large, rigid molecule containing a small fluorescent moiety, the rotational diffusion corresponds to the rotation of the entire assembly. More complicated scenarios are encountered when segmental motion exists between the fluorescent moiety and the rest of the molecule. These will be considered in more detail later.

Since the size of the molecule and the viscosity of the medium largely determine the rotational diffusion of a molecule, fluorescence anisotropy can be used to elucidate the molecular weight of fluorophores. Consider the case of a spherical molecule, where the rotary diffusion coefficient, $D_o$, is given by Equation (65)

$$D_o = \frac{kT}{6\eta V}$$

(65)
where \( k \) is the Boltzmann constant, \( T \) is the temperature in Kelvin, \( \eta \) is the viscosity of the solution and \( V \) is the volume of the rotating body, which is equal to the volume of the particle plus the volume of the hydration sphere. The rotation of molecules can be described by considering them as ellipsoids of revolution. This type of treatment is given elsewhere and is beyond the scope of this discussion. The spherical particle can, however, be treated in a relatively simple manner. The depolarization can be ascribed to rotation about three primary axes, each with a rotational correlation time, \( \phi_1 \), \( \phi_2 \), and \( \phi_3 \). The symmetry of the spherical particle dictates that all three rotational correlation times are identical and related to the rotational diffusion by Equation (66)

\[
\phi_1 = \phi_2 = \phi_3 = \phi_0 = \frac{1}{6D_o}
\]

(66)

Combining Equations (65) and (66) shows that, in the case of spherical species, the rotational correlation time is given by Equation (67)

\[
\phi = \frac{\eta V}{RT}
\]

(67)

The discussion thus far has focused on a single molecule, but the previous equations can be applied to a quantity of molecules via Avogadro’s number and the rotational correlation time is then given by Equation (68)

\[
\phi = \frac{\eta V}{RT}
\]

(68)

where \( R \) is the gas constant. The Perrin equation can then be written as Equation (69)

\[
\frac{1}{r} = 1 + \frac{RT}{\eta V} \tau
\]

(69)

More often, the Perrin equation is written as Equation (70)

\[
r = r_o + \frac{\eta V}{RT} \tau r_o
\]

(70)

which directly relates the measured anisotropy to the volume of the rotating species and the viscosity of the environment surrounding it.

3.9.3 Perrin Plot

A useful extension of the Perrin equation is based on the temperature/viscosity dependence of the anisotropy. The Perrin equation can be rearranged in the form of a linear equation as shown in Equation (71).

\[
\frac{1}{r} = \frac{R \tau}{V \tau_o} \frac{T}{\eta} + \frac{1}{r_o}
\]

(71)

The Perrin plot is then constructed by plotting the reciprocal anisotropy as a function of the temperature and viscosity. The \( y \)-intercept of this plot, which represents anisotropy at infinite viscosity, yields the intrinsic anisotropy. Furthermore, the slope of this plot is given by Equation (72):

\[
\text{slope} = \frac{R \tau}{V \tau_o}
\]

(72)

The Perrin plot is illustrated in Figure 11.

Experimentally, the Perrin plot is constructed either by varying the temperature of the solutions over a range of values, or by holding the temperature constant and varying the viscosity. In this manner, the intrinsic anisotropy and the molecular volume can be determined.

3.9.4 Association Reactions

Fluorescence anisotropy can be used to monitor association reactions. This is due to the dependence of the anisotropy on the size of the rotating species, as is evident from the volume term in Equation (68). Consider a system where a fluorophore may associate with a larger molecule, an example of which is the binding of proflavin to DNA. Upon binding, the rotational correlation time of the fluorophore will change substantially and be approximated by the rotational correlation of the much larger DNA molecule. This can be easily followed by use of fluorescence anisotropy. In fact, the degree of binding is directly related to the measured anisotropy. Equation (44) shows that anisotropy values are additive, where the observed anisotropy is an average of the individual components, weighted by the fractional intensity of each species. Hence

![Figure 11 Idealized Perrin plot of a fluorescent molecule in a homogeneous solution.](image-url)
Equation (73) shows that for a system which consists of a fluorophore that can bind to another system,

\[ r_{\text{obs}} = f_tr_t + f_br_b \]  \hspace{1cm} (73)

where \( f_b \) and \( f_t \) represent the fractional intensity of the free and bound species, and \( r_b \) and \( r_t \) are the anisotropy of the two species. In many cases, the anisotropy of the free and bound fluorophore can be determined experimentally by examining the fluorophore alone and in the presence of an abundance of the species to which it binds. In such cases, the fraction of fluorophore that is bound can be given by Equation (74).

\[ f_b = \frac{r_{\text{obs}} - r_t}{r_b - r_t} \]  \hspace{1cm} (74)

Equation (74) assumes that the quantum efficiency does not change upon binding. If the quantum efficiency does change a more complicated expression that accounts for the quantum efficiency must be employed.

3.9.5 Time-dependent Anisotropy

When a sample is excited with a pulse of light, rather than steady-state illumination, the degree of polarization will decrease as a function of time. The decay of the fluorescence anisotropy is given by Equation (75)

\[ r(t) = r_0 e^{-t/\phi} \]  \hspace{1cm} (75)

where the decay rate is dependent on the rotational correlation time and the maximum at \( t = 0 \) is equal to the intrinsic anisotropy. The potential utility of the technique should be apparent, as the intrinsic anisotropy and the rotational correlation time can be determined from a single experiment. Furthermore, a complex mixture consisting of either multiple fluorophores or a single fluorophore in multiple environments will have anisotropies that decay as a multiple exponential as shown in Equation (76)

\[ r(t) = r_0 e^{-t/\phi_i} \]  \hspace{1cm} (76)

where \( \phi_i \) is the rotational correlation time of the \( i \)th component.

It should be noted that the anisotropy decay is not dependent on the fluorescence lifetime. This is a fundamental difference between time-dependent and steady-state anisotropy measurements. Recall from the Perrin equation (Equation (64)) the dependence of the steady-state anisotropy on the fluorescence lifetime. Consider the case of the fluorescent probe pyrene, which typically has a fluorescence lifetime in the order of 200 ns. Since the fluorescence lifetime is much longer than the rotational correlation time, the emission will be completely depolarized. In contrast, useful information can be obtained from such systems by measuring the anisotropy decay.

Experimentally, the anisotropy decay is obtained by collecting the parallel and perpendicular components as a function of time. Hence, the anisotropy is calculated using Equation (77).

\[ r(t) = \frac{I_\parallel(t) - I_\perp(t)G}{I_\parallel(t) + 2I_\perp(t)G} \]  \hspace{1cm} (77)

Figure 12 shows typical polarized fluorescence decays and the calculated anisotropy decay.

A major advantage of determining time-dependent anisotropy is that the anisotropy decay can reveal whether the fluorophore is able to rotate freely or whether its molecular motion is restricted. This can be the case when a fluorescent probe is dissolved in a highly ordered membrane system, or a larger molecule experiences segmental motion. In these cases, the anisotropy will decay to a nonzero value as shown in Figure 13.

The nonzero value to which the anisotropy decays is referred to as the limiting anisotropy \((r_\infty)\) and is described by Equation (78).

\[ r(t) = (r_0 - r_\infty)e^{-t/\phi_i} + r_\infty \]  \hspace{1cm} (78)

Equation (78) assumes a simple hindered rotor that is symmetrical, but often satisfactorily explains more complex species. A useful equation, which relates the limiting anisotropy to the degree of rotational hindrance,
is shown in Equation (79)

\[ \frac{r_\infty}{r_o} = \frac{3 \cos^2 \theta - 1}{2} \]  
(79)

where \( \theta \) is referred to as the order parameter. See the references cited in ‘Further Reading’ for more sophisticated treatments that have been utilized.

4 BASIC FLUORESCENCE INSTRUMENTATION

4.1 General Instrumentation

In the simplest of cases, a fluorimeter consists of three components. These include a light source, a sample holder, and a detector. As an illustrative example, consider the apparatus Stokes used to examine quinine solutions. Sunlight served as the source, a glass tube held the solution of quinine and his eye served as the detector. It should be noted, however, that this was a special case where the fluorescence was easily visible because the excitation wavelength was in the ultraviolet and the fluorescence emission was easily visible as blue light. In most cases, a method of wavelength discrimination is employed to select both the excitation and observation wavelengths. Therefore, practically all fluorimeters will have at least five components, which include the source, two wavelength discriminators, a sample holder, and a detector (Figure 14).

While specific configurations may vary and new technology is continually incorporated in commercial instruments, the fundamental components are invariant and will be covered in this discussion. For fear of becoming dated, we have refrained from discussing specific commercial instruments and will instead introduce the basic components and list the various technologies that are commonly employed.

4.2 Light Sources

There are two primary considerations when choosing a light source, the range of wavelengths it produces and the intensity at which it produces them. A source can produce a spectrum with characteristics of either a continuous or line emission. Most sources produce light with a broad continuous emission with some spectral lines superimposed, a prime example being the xenon lamp.

4.2.1 Xenon Lamp

The xenon lamp is probably the most commonly used source in fluorescence spectrophotometers. It produces a relatively continuous emission ranging from \( \sim 200 \text{ nm} \) up to wavelengths in the infrared region, although the intensity diminishes significantly below \( \sim 270 \text{ nm} \). The spectrum of a xenon lamp is shown in Figure 15.

Figure 15 illustrates the wavelength dependence of the lamp intensity, which results in a distorted excitation

![Figure 13](image1.png) **Figure 13** Time-resolved anisotropy of a system exhibiting a limiting anisotropy.

![Figure 14](image2.png) **Figure 14** Schematic diagram of a basic fluorescence spectrophotometer.

![Figure 15](image3.png) **Figure 15** Emission spectrum of a typical xenon lamp.
spectrum. Corrections to account for this dependence will be discussed in section 4.5. Less expensive commercial instruments will often use a 150 W xenon lamp, while more expensive research grade instruments typically benefit from lamps rated from 450 to 750 W. The more powerful lamp directly affects the sensitivity of the instrument and can lead to extremely low limits of detection.

4.2.2 Mercury Lamps

Mercury lamps are typically more intense in the ultraviolet region than xenon lamps, but they only produce light at certain spectral lines. Therefore, these lamps can only be used in cases where the spectral output of the lamp is coincident with the excitation requirements of the fluorophore. Thus, mercury lamps typically find use in specialized applications, not in a general use fluorimeter. Another lamp, although not commonly employed, is the xenon–mercury lamp, which is a mercury lamp produced with amounts of xenon gas present. The ultraviolet output is greater than the xenon lamp, but the spectral output is not as smooth.

4.2.3 Lasers

Lasers are finding increased use as excitation sources in fluorescence instrumentation. While the cost of a laser is usually a significant consideration, the high power and spectral purity result in frequent use. A major drawback of a typical laser source is the limited range of wavelengths produced. Furthermore, the wavelengths produced are typically in the red or infrared region (Nd:yttrium aluminum garnet 1064 nm, Ti:sapphire 600–1000 nm). This is a region not useful for fluorescence excitation. The laser light is typically modified in the following manner. The fundamental wavelength of the laser is frequency doubled (or tripled) to produce light in the UV/VIS region. This is then used as an excitation source for a second dye laser, which will produce light of a longer wavelength possessing various degrees of tunability, depending on the laser dye that is used. Lastly, the output from the dye laser is frequency-doubled and tuned to the desired wavelength.

Even though much of the intensity is lost during the various conversions, the resulting excitation beam can offer significant advantages over conventional sources. A significant advantage of using a laser source is the fact that many lasers can operate in a pulsed mode, making them an ideal source for measurements in the time domain. Many laser systems are now routinely capable of producing pulses of a few picoseconds and some commercial systems can produce pulses as short as 100 fs. While a full discussion of laser sources is beyond the scope of this text, the reader should be aware of their potential applicability, especially since some relatively inexpensive dye and solid-state diode lasers are now becoming commercially available.

4.2.4 Flash Lamps

One of the most routinely used pulsed sources for fluorescence lifetime measurements is the flash lamp. A flash lamp consists of a lamp filled with gas and two electrodes that are used to produce an electrical discharge through the gas. Flash lamps typically produce lamp pulses of a few nanoseconds and the spectral output depends on the type of gas that is used. The most common gas used is nitrogen, although hydrogen is often used when shorter wavelengths are desired. The discharge of the electrodes is typically controlled with a thyatron tube, which discharges at a particular frequency independent of the capacitance of the lamp. This results in a flash that is very reproducible.

4.3 Wavelength Selectors

Wavelength selectors are used to selectively transmit a particular wavelength of light. The various technologies that are available can be categorized as either filters or monochromators. Filters have the ability to absorb certain wavelengths of light, but are fixed for a given filter. Monochromators have the ability to scan a region of the spectrum. Thus, monochromators must be used to obtain excitation or emission spectra. Both filters and monochromators have advantages for certain applications.

4.3.1 Filters

Optical filters are made from glass or quartz that has been produced with an amount of certain dyes that absorb certain wavelengths of light. Optical filters can be manufactured as either cut-on filters or cut-off filters. Cut-on filters absorb light up to a characteristic “cut-on” wavelength, above which they transmit radiation. Cut-off filters transmit light up to a certain wavelength and absorb wavelengths greater than the “cut-off”. Figure 16 shows transmission curves for a series of filters that can be obtained from one of several manufacturers. Optical filters offer the significant advantages of high light throughput and low cost, but suffer from a lack of selectivity.

Interference filters consist of a coated dielectric material placed between two semitransparent films. Interference of the incident light will occur between the two films and only the wavelengths that interfere constructively will be transmitted through the filter. Interference filters offer the advantage of higher selectivity over optical filters, but still pass a relatively broad range of wavelengths and their transmission is poorer than that of optical filters.
4.3.2 Monochromators

The primary component of a monochromator is the dispersive element. Historically, a prism was used as the dispersive element, but today gratings are exclusively used. A monochromator consists of a grating and a set of slits to control the amount of light (and bandwidth) that enters and exits the monochromator. The type of grating and the geometry of the monochromator determine the spectral resolving power and the throughput of the monochromator. Even though the efficiency is usually higher in a system using optical filters, most commercial and research instruments are equipped with monochromators as wavelength-selective devices, due to their versatility.

4.4 Detectors

Although some systems are available that use multichannel detectors, such as photodiode arrays (PDAs) and charge-coupled devices (CCDs), most fluorescence spectrophotometers use photomultiplier tubes (PMTs) for detection. PMTs offer the advantage of inherent gain, where $10^6$ to $10^9$ electrons may be produced for each photon. The dark current of the PMT typically determines the detection limit of a fluorimeter. The dark current is the signal that is measured in the absence of light, due to a random nonphoton-induced cascade of electrons. Since the dark current is related to temperature, the PMT is often cooled, typically resulting in much lower limits of detection.

An additional consideration is the spectral response of the PMT, which is wavelength-dependent. Many types of PMTs are manufactured that are optimized for various wavelengths. Figure 17 shows the detector response curves for two commercial PMTs.

4.5 Spectral Correction

In an ideal fluorimeter, the measured excitation spectrum would be the same as the absorption spectrum. In reality
this is not the case, since most components of the fluorimeter are wavelength-dependent, particularly the source. The profile of the excitation spectrum will be significantly lower in the ultraviolet region, due to the decreased intensity of the xenon source. Other instrumental artifacts will also be present due to bias in the throughput of the monochromators and the spectral sensitivity of the detector. The most common type of correction that is applied uses a reference signal, as shown in Figure 18.

In this type of correction, a small fraction of the excitation beam is split prior to the sample. This light is then used to excite a fluorescent “quantum counter”. The quantum counter is a material that produces a signal proportional to the intensity of the incident light. One of the most commonly used quantum counters is rhodamine B. A concentrated solution of rhodamine B in ethylene glycol absorbs virtually all light from 220 to 600 nm and gives a fluorescence signal that is proportional to the intensity of the excitation source. The excitation spectrum can then be recorded using a ratio of the sample PMT signal to that of the reference PMT signal, effectively correcting for the bias in the excitation source.

Schemes also exist for correcting the emission spectra, although they are less often employed. They typically are based on the measurement of a known emission source, such as a tungsten filament. The measured response can then be modified to produce the known spectrum, thus generating a correction factor that can be subsequently applied to a measured emission spectrum. It should be noted that spectral correction is typically only necessary for the determination of quantum efficiencies and overlap integrals in energy transfer studies.

4.6 Measurement of Fluorescence Lifetimes

While a complete discussion of the instrumentation involved in the measurement of fluorescence lifetime is beyond the scope of this text, we wish to present the reader with a basic overview of the two main types of experiments that are used to measure fluorescence decays. More detailed information can be found in Fluorescence Lifetime Measurements, Applications of.

4.6.1 Time-domain Experiments

One of the most common configurations for measurement of lifetimes involves exciting the sample with a short pulse of light and monitoring the fluorescence intensity of the sample as a function of time. If the pulse is sufficiently short (i.e. a δ-pulse) the fluorescence signal will decay exponential from a maximum value at time zero, as shown in Equation (80):

\[ I(t) = I_0 e^{-t/\tau} \]  

where \( I_0 \) is the fluorescence intensity at \( t = 0 \), and \( \tau \) is the fluorescence lifetime. Measurements are typically completed in one of three configurations, each of which will be discussed briefly.

4.6.1.1 Time-correlated Single-photon Counting

In the time-correlated single-photon counting technique, the sample is illuminated with a pulse of light of short duration. This ensures that a given molecule will only be excited once during the pulse. At the instant a population of molecules are excited, they will randomly begin returning to the ground state by emitting a photon, the probability of which is described by the fluorescence lifetime (see section 3.7). Figure 19 shows schematically the time-correlated single-photon counting technique.
When the source produces a pulse of light, the trigger detector sends a signal to start the time-to-amplitude converter (TAC). The TAC then linearly increases the voltage on a capacitor within the TAC until a “stop” signal is received from the sample detector. After the “stop signal” the voltage is measured on the capacitor, the magnitude of which correlates to the time of detection. The voltage is sent to a multi-channel analyzer, which stores the event in a histogram representing the delay time associated with the emission event. This process is repeated until a representative histogram is built up representing the time distribution of the emission events. The data can then be deconvolved (if necessary) and are typically analyzed with a least-squares treatment. Details of these procedures can be found elsewhere and will not be covered in this discussion.

### 4.6.1.2 Pulse Sampling (Stroboscopic) Method

In the pulse sampling method, the source is pulsed repetitively and the detector PMT is gated to operate for short periods of time, relative to the fluorescence lifetime. In this manner, the detector only measures fluorescence for a certain time-window during each cycle. The delay between the excitation pulse and the measurement window is varied, such that a profile showing the intensity as a function of time is collected. The process is illustrated in Figure 20.

An alternative method exists, where the PMT gain is held constant and the collection of data is gated. A sampling oscilloscope is used to measure the intensity of the PMT during very short time-windows and a multichannel analyzer is used to construct the delay curve. An advantage of this sampling technique is that much shorter sampling pulses can be measured (~30 ps).

### 4.6.2 Frequency-domain Experiments

In frequency-domain measurements, a steady-state source is used, but its intensity is varied in a sinusoidal manner. Since the intensity of fluorescence emission is directly related to the intensity of the source, the emission intensity will vary with the same frequency as the source. There is, however, a time lag between excitation and emission due the fluorescence lifetime. This time lag results in a phase shift (φ) between the oscillation of the source and the emission (Figure 21).

Additionally, the signal is demodulated (m) relative to the modulation of the excitation source. These parameters are related to the lifetime as shown in Equation (81)

\[ \tan \phi = w \tau_p \]  

where w is the circular frequency of the modulation and \( \tau_p \) is the phase lifetime. Additionally, the demodulation, m, is related to the lifetime as shown in Equation (82)

\[ m = (1 + w^2 \tau_m^2)^{-1/2} \]  

where \( \tau_m \) is the demodulation lifetime. Equation (83) applies to single exponential decays.

\[ \tau = \tau_p = \tau_m \]  

It should be noted that more complicated treatments are needed for multiexponential decays, discussions of which can be found in several references. See the article Detectors, Absorption and Luminescence for detailed discussion of instrumentation.
The use of luminescence in analytical chemistry has gained wide acceptance, due in part to the inherent sensitivity and selectivity of the technique.

Absorption and Luminescence Probes

William E. Acree, Jr  
University of North Texas, Denton, TX, USA

1 Introduction

Absorption and luminescence probes are molecules or ions whose spectral properties depend upon the chemical nature of the solubilizing media in the immediate vicinity of the probe molecule. Probe character is generally evidenced by the appearance of new spectral bands, shifts in the absorption or emission wavelengths, or by changes in emission intensities. Probe molecules have been used to determine solvent polarity and solvent acidity/basicity, pH, microviscosity, temperature and/or presence of specific ions/molecules. When combined with fluorescence lifetime measurements, absorption and luminescence probes can provide additional information regarding diffusion coefficients in probe excimer formation, fluidity in lipid vesicles, and rates of intermolecular collisions in quenching experiments.

1 INTRODUCTION

Spectroscopic probe techniques are becoming increasingly popular for examining the surface microenvironment of chromatographic materials, surfactant micellization/adsorption, polymer/surfactant interactions, cyclodextrin cavities and inclusion complexes, sol–gel and inorganic glass formations, microemulsions and other molecularly organized solvent media. As typical examples, Street and Acree(1) estimated the effective dielectric constant of cyclodextrin (CD) on the basis of the measured fluorescence properties of pyrene-1-carboxyaldehyde [3029-19-4]. Stahlberg and Almgren(2) showed that the fluorescence properties of pyrene (Py) [129-00-0] could be used to investigate how the polarity of chemically modified silica surfaces varied with the surrounding solvent composition. For aqueous–methanol and aqueous–acetonitrile mixtures, the author noted large differences between the organic modifier interactions with RP-2 surfaces. Methanol decreased the polarity by hydrogen-bonding to the free silanol groups on the surface, whereas acetonitrile increased the polarity by absorbing to the alkyl chains and thus forming a layer of “more or less freely moving” organic molecules on the surface. Helburn et al.(3) subsequently studied the polarity and heterogeneity of reversed-phase chromatographic surfaces in equilibrium with aqueous–acetonitrile and aqueous–methanol solvent mixtures. Spectroscopic measurements using 2,6-dichloro-4-(2,4,6-triphenyl-N-pyridino)phenolate (ET-33) [121792-58-3] and N,N-diethyl-4-nitroaniline [2216-15-1] probe molecules indicated that the stationary phase is considerably more polar than bulk alkane solutions. Residual surface silanol groups strongly influenced the chemical and solvational properties of the interphase region.

Burrell and Hurtubise(4,5) employed solid-surface fluorescence methods and benzoquinoline probe molecules to investigate chromatographic interactions of polycyclic aromatic nitrogen heterocycles (PANHs) adsorbed onto water-deactivated silica gels. PANHs exist in both neutral and protonated forms, depending upon the acidity of the surrounding microenvironment. Protonation of a PANH molecule by a surface silanol results in the loss of fluorescence emission fine structure and a redshift in the emission wavelengths. From observed benzo[h]quinoline [230-27-3] emission spectra the authors were able to estimate the neutral to protonated form ratios of the various silica gel–water content compositions studied. Maximum localization of benzo[h]quinoline occurred near 5% water on surface sites that protonated the probe molecule.
The last three examples pertained to characterization of chromatographic stationary phases. The observed spectral response of the probe molecule was used to elucidate the chemical and physical properties of the solvated stationary phase. Spectroscopic studies have identified several hundred organic and organometallic compounds having absorption and fluorescent spectral properties that are highly sensitive to changes in solvent polarity, temperature, viscosity, solvent acidity/basicity and/or the presence of specific ions/molecules. Theoretically, any one of these compounds can serve as a spectroscopic probe molecule. From a practical standpoint, it is extremely time-consuming to fully characterize and understand a given molecule’s spectral behavior. Consequently, only a relatively small number of compounds have actually been recommended as absorption and luminescence probe molecules. Reasonable efforts have been made to identify several suitable absorption probes and several suitable luminescence probes for each type of analytical application. Depending upon the sample being studied and instrumentation availability, a luminescence probe may be preferred to an absorption probe, and vice versa. A more in-depth discussion of probe methods, including the different types of measurable physical/structural parameters, can be found in a lengthy review article devoted to fluorescent probe molecules.

2 ULTRAVIOLET/VISIBLE ABSORPTION SOLVENT POLARITY PROBES

Molecular interactions between a dissolved chromophore and surrounding solvent molecules often lead to noticeable changes in the chromophore’s ultraviolet/visible (UV/VIS) absorption spectrum. Change in position, intensity or peak shape that occurs when a chromophore is transferred from gas phase to a solvent is referred to as solvatochromism. The most common form of solvatochromic behavior is the change in position of absorption band maxima whenever the chromophore is dissolved in different organic solvents or binary aqueous–organic mixtures having different composition. The direction of this wavelength shift generally depends upon relative magnitude of dipole moments of ground and excited states of the chromophore as shown in Figure 1.

Initially, the chromophore and surrounding solvent molecules are in the ground electronic level (S0) and in the ground state configuration. Time averaged ground state configuration would have the dipole moments of solvational sphere solvent molecules aligned with the chromophore’s dipole moment. Upon absorption of a photon, the chromophore is excited to the S1 (or perhaps higher) electronic excited state, which is accompanied by a corresponding change in dipole moment. On the same time scale as the absorption process, there is a redistribution of electrons in solvational sphere molecules to better align with the chromophore’s new dipole moment. There is insufficient time, however, for the physical re-orientation of the solvational sphere molecules or for any change in solvational sphere composition. According to the Frank–Condon principle, electronic transitions are fast compared to nuclear motions and solvent molecule movements. Lack of molecular re-orientation for both absorption and emission spectral transitions leads to preferential solvation of ground or excited state, and a shift in the energy of the electronic transition. Positive solvatochromism is, by definition, a bathochromic shift (longer wavelength, lower energy) with increasing solvent polarity. Conversely, an hypochromic shift (shorter wavelength, higher energy) of absorption band with increasing solvent polarity is called negative solvatochromism.

At a more theoretical level, numerous mathematical expressions have been derived during the past 40 years...
that relate the frequency of the absorption band maxima, \(v_{\text{max}}\), to the refractive index, \(n\), and the dielectric constant, \(\varepsilon\), of the solubilizing medium. Two examples of such treatments are the Bekarek and Bayliss models which are given by Equations (1) and (2), respectively.

\[
v_{\text{max}} = A + \frac{n^2 - 1}{n^2} \frac{\varepsilon + 1}{\varepsilon} C \tag{1}
\]

\[
v_{\text{max}} = A + \left\{ n^2 - \frac{n^2 - 1}{2n^2 + 1} \right\} C \tag{2}
\]

In real terms \(A\) is related to the position of the absorption maxima in the gas phase spectrum, and \(C\) incorporates several solute properties and physical constants. Intermolecular solute–solvent interactions are highly complicated in nature, and extremely difficult to understand. To date, no one single theoretical treatment satisfactorily explains the observed solvatochromic behavior that results whenever different chromophores are dissolved in various microenvironments.

Lack of a single, comprehensive theoretical expression for predicting solvatochromic wavelength shifts, combined with the inadequacy of defining solute–solvent interactions in terms of simple functions of solvent properties, led to the development of solvent polarity scales deduced from the spectral behavior of select chromophores. One of the most widely used empirical scales of solvent polarities is the \(E_T(30)\) scale based upon Equation (3):

\[
E_T(30) \text{ (in kcal mol}^{-1}\text{)} = \frac{28\,591}{\lambda_{\text{max}} \text{ (in nm)}} \tag{3}
\]

the charge-transfer absorption of the zwitterionic 2,6-diphenyl-4-(2,4,6-triphenyl-N-pyridinio)phenolate molecule (ET-30) \[10081-39-7\]). The zwitterionic compound, also known as the Dimroth and Reichardt’s betaine, exhibits one of the larger observed solvatochromic effects of any known organic molecule. Wavelength shifts amount to several hundred nanometers in going from a very polar solvent (\(\lambda_{\text{max}} \approx 453\) nm in water) to a nonpolar solvent (\(\lambda_{\text{max}} \approx 925\) nm in hexane). In fact, the apparent color of solutions containing the ET-30 absorption probe molecule serves as a rough indicator of solvent polarity. Methanolic solutions of the dye molecule appear wine red (\(\lambda_{\text{max}} \approx 515\) nm), whereas the apparent color changes to deep blue (\(\lambda_{\text{max}} \approx 622\) nm) when the dye is dissolved in acetonitrile. Numerical values of the \(E_T(30)\) solvent polarity parameter are calculated from the wavelengths of maximum absorbance using Equation (3). Similarly, the \(E_T(33)\) scale is defined in terms of the spectral properties of the ET-33 molecule.

Other examples of spectroscopically deduced polarity measures are the \(Z\) and \(Z'\) scales suggested by Kosower.\(^{(9)}\)

These two scales are defined by Equation (4):

\[
Z(\text{or } Z') = \frac{28\,591}{\lambda_{\text{max}} \text{ (in nm)}} \tag{4}
\]

The \(E_T(30), E_T(33)\), \(Z\) and \(Z'\) scales are known as single parameter scales in that the solvent is described with only a single experimentally determined parameter. Multiparameter approaches exist for expressing solvent polarity effects in terms of separate contributions from polarizability, and hydrogen-bond donor and acceptor interactions. For example, Kamlet, Taft and coworkers\(^{(10,11)}\) introduced the \(\pi^*\) scale of solvent dipolarity/polarizability for representing solute–solvent interactions in the absence of strong forces such as hydrogen-bonding or ion–dipole interactions. Numerical values of \(\pi^*\) are calculated using the \(\pi \rightarrow \pi^*\) absorption band of a series of solutes, such as 4-ethynitrobenzene \[100-12-9\] or \(N,N\)-diethyl-4-nitroaniline. Table 1 lists several spectroscopic probes that have been recommended for \(\pi^*\) determinations, along with their corresponding mathematical equations. The \(\alpha\)– and \(\beta\)– scales of hydrogen-bond acceptor and donor interactions have also been derived from solvatochromic measurements. A more complete list of UV/VIS absorption spectroscopic probes and solvent polarity scales is published elsewhere.\(^{(7,8)}\)

Solvent polarity probes have been used in analytical chemistry to characterize chromatographic stationary and mobile phases, and to describe how solute retention times vary with organic modifier composition in the case of aqueous–organic mobile phase mixtures. Johnson et al.\(^{(13)}\) reported that plots of logarithm of capacity factor, \(\log k'_{\text{solute}}\), versus \(E_T(30)\) parameter were better descriptors of solute retention in binary aqueous–acetonitrile and aqueous–methanol mobile phases than were \(\log k'_{\text{solute}}\) versus percent organic modifier graphs. The authors’ data analysis was summarized in the form of a frequency histogram of the squared linear correlation coefficient, \(r^2\). The histogram for the \(E_T(30)\) correlations encompasses approximately 98.2% of the

\(^a\) For a more complete listing of spectroscopic probes see Kamlet et al.\(^{12}\)

\(^b\) \( \nu_{\text{max}} \) is the observed absorption maximum in wavenumbers \(( \times 10^{-3} \text{ cm}^{-1})\).

332 data sets considered for \( r^2 \geq 0.95 \). Only 89.2% of the data sets are contained in the percent organic modifier histogram.

Carr and coworkers\(^{14,15} \) applied the solvatochromic comparison method and linear solvation energy relationships in determining what solute chemical and physical characteristics govern retention in reversed-phase HPLC. The logarithm of the solute capacity factor was expressed as Equation (5):

\[
\log k'_{\text{solute}} = \text{intercept} + M(\delta_s^2 - \delta_m^2) V_{\text{solute}} + S(\pi_s^* - \pi_m^*) \tau_{\text{solute}} + A(\beta_s - \beta_m) \alpha_{\text{solute}} + B(\alpha_s - \alpha_m) \beta_{\text{solute}}
\]

(5)

where \( V_{\text{solute}} \) denotes that the molar volume of the solute, \( \delta \) is the Scatchard–Hildebrand solubility parameter, \( \pi^* \) represents the polarizability/dipolarity parameter, and \( \alpha \) and \( \beta \) refer to the hydrogen-bond acidity and basicity values. Each solute property is multiplied by a term that represents the difference in the complementary “solute” properties for the mobile (m subscript) and stationary (s subscript) phases. The intercept and four curve-fit coefficients \((M, S, A \text{ and } B)\) are obtained through a multilinear least-squares regresional analysis. Numerical values of the coefficients determine which of the possible molecular interactions control solute retention. The more important contributions have the larger numerical coefficients. In the case of chromatographic retention behavior of a series of aromatic solutes in reversed-phase HPLC with a binary aqueous–acetonitrile mobile phase, Carr and coworkers found that solute size and hydrogen-bond basicity were the principle factors controlling retention. Multilinear correlations between pH and spectroscopically deduced solvent polarity parameters have been suggested for the standardization of potentiometric pH sensors in mixed aqueous–organic solvents.\(^{16} \)

UV/VIS absorption probes have also been used to examine preferential solvation that occurs whenever a solute molecule is dissolved in a binary solvent mixture. Preferential solvation arises whenever the proportion of molecules of a given solvent component within the probe’s solvational sphere is not equal to its bulk mole fraction composition. “True preferential solvation” is extremely difficult to theoretically model, and most published
approaches have assumed an idealized set of conditions in which the measured spectral response in the binary solvent mixture, $R_{\text{solute, AB}}$, is given by Equation (6):

$$R_{\text{solute, AB}} = X_A R_{\text{solute, A}} + X_B R_{\text{solute, B}}$$

(a weighted mole fraction average of the probe’s spectral response in the two neat solvents, $R_{\text{solute, A}}$ and $R_{\text{solute, B}}$). For UV/VIS absorption solvent polarity probes the spectral response is the reciprocal of the maximum absorbance wavelength, $1/\lambda_{\text{max}}$, and $X_A$ and $X_B$ refer to the mole fraction compositions of solvents A and B in the solvational sphere. Phillips and Brennecke(17) used Equation (6) to estimate the degree of preferential solvation around the solvatochromic probe phenol blue [2150-58-5]. Solvent mixtures investigated included acetone–cyclohexane, triethylamine–cyclohexane, ethyl butyrate–cyclohexane, cyclohexanone–cyclohexane, acetoephone–cyclohexane and acetonaphone–toluene. In most cases spectroscopically obtained local compositions compared reasonably well with values calculated from thermodynamic models and measured solubility data. More sophisticated preferential solvation treatments take into account molecular size disparity and incorporate molar absorbptivities for the different assumed solvational species.

## 3 ABSORPTION AND LUMINESCENT SPECIFIC ION AND MOLECULAR RECOGNITION PROBES

The idea of chemically modifying ionic or molecular analytes through complexation and/or derivatization in order to make the species more amenable to a particular spectroscopic analysis is not new. Over the past 50 years several hundred chelating ligands have been developed for the spectrophotometrical analysis of metal ions, and numerous derivatizing agents synthesized for spectrophotometric detection in conjunction with liquid chromatography and fluorescence microscopy. Probes have even been designed for select classes of biological molecules. For purposes of this review, such chelating agents and derivatizing agents are classified under the broad umbrella of absorption and fluorescent specific ion and molecular recognition probes.

Most chelating and derivatizing agents possess a chromophoric and/or fluorophoric moiety, which usually is an aromatic moiety. Such probes achieve their recognition specificity for the desired analyte either through selective complexation or chemical reaction. In the case of complexation, the ability of the probe to form molecular complex(es) is governed by the value of the formation equilibrium constant, which may depend upon analyte-probe molecular size/shape compatibility (i.e. crown ethers and crypts). Derivatizing agents, on the other hand, achieve their selectivity through highly specific chemical reactions that occur between given functional groups on the analyte and probe molecule. A derivatizing agent thus reacts only with those molecules present in the mixture that contain the given functional group. Table 2 lists several of the common derivatizing agents that are used in HPLC to achieve enhanced absorption and fluorescence detection.

Absorption and luminescent recognition probes are often used in the construction of fiber-optic sensors for remote chemical detection. In the simplest version, the probe molecule is immobilized at the tip of an optical fiber. Light is transmitted from the radiation source to the sample through the fiber. The reflected radiation enters a second optical fiber and enables the changes in the spectral properties of the immobilized probe molecule in contact with the analyte solution to be recorded. The analyte concentration is calculated from the measured absorbance and/or fluorescent emission intensity. Specific ions that have been detected with fiber-optic chemical sensors include Cl−, Br− and I− based upon fluorescence quenching of glass-immobilized quinoline [91-22-5], Be2+ and Al3+ using the immobilized fluorescent morin [480-16-0], and alkali metal ions using complexation-induced spectral changes of fluorescent crown ethers in poly(vinyl chloride) films.(21) Extensive compilations of complexing agents for the different metal ions can be found in published monographs(22–24) devoted to the subject.

Chemical sensors are also able to monitor the concentration levels of ammonia, carbon dioxide, oxygen, hydrogen cyanide and several other gaseous molecules. Chromophores employed in the absorbance-based NH₃ sensors include the acid–base indicators chlorophenol red [4430-20-0], brom cresol purple [115-40-2], brom cresol green [62625-32-5], brom thymol blue [76-59-5] and bromphenol blue [115-39-9]. Fluorescence intensity-based NH₃ sensors have contained acridine orange [10127-02-3], carboxy-4′,5′-dimethylfluorescein, 2,7-bis(2-carboxyethyl)-5-carboxyfluorescein [85138-49-4] and 8-hydroxy-7,1,3-trisulfonic acid [27828-00-3] as probe molecules.(25) Similarly, cresol red [1733-12-6], phenol red [143-74-8], neutral red [553-24-2], bromothymol blue, brilliant yellow [3051-11-4], m-cresol purple [2303-01-7] and 3-nitrophenol [554-84-7] are used in CO₂ chemical sensors. The measured absorbance of the acid–base indicator is related to the CO₂ concentration in the sample.(26) Probes utilized in the NH₃ and CO₂ sensors actually respond to hydrogen ion, which is related to the analyte concentration through acid–base equilibria.

For example, in a typical ammonia gas sensor, the ammonia reacts with an acidic pH indicator according to...

The reaction in Equation (7):

\[
\text{HIn} + \text{NH}_3 \rightleftharpoons \text{In}^- + \text{NH}_4^+ \quad (7)
\]

The unprotonated form of the indicator is detected by either a fluorescence or an absorbance measurement. In the latter case, the measured absorbance, \(A\), is related to the ammonia concentration in the sample solution by Equation (8):

\[
A = \frac{\varepsilon b K_{eq} C_{\text{In}} [\text{NH}_3]_{\text{sample}}}{C_{\text{NH}_3} + K_{eq} [\text{NH}_3]_{\text{sample}}} \quad (8)
\]

where \(\varepsilon\) denotes the chromophore’s molar absorptivity, \(b\) is the effective pathlength at the tip of the fiber optic probe, \(K_{eq}\) represents the conditional equilibrium constant for proton transfer, \([\text{NH}_3]_{\text{sample}}\) is the ammonia concentration in the sample, and \(C_{\text{In}}\) and \(C_{\text{NH}_3}\) refer to the stoichiometric molar concentrations of the indicator and ammonia, respectively. Inspection of Equation (8) reveals that a nearly linear response occurs at low ammonia concentrations whenever \(C_{\text{NH}_3} \gg K_{eq} [\text{NH}_3]_{\text{sample}}\). The calibration curve is linearized as a double reciprocal \(1/A\) versus \(1/[\text{NH}_3]_{\text{sample}}\). A similar expression holds in the case of a fluorescent probe molecule. Chemical sensors
for NH₃ and CO₂ with suitable modification permit measurement of pH directly.

Molecular oxygen can be conveniently detected with fluorosensors that rely on dynamic quenching of suitable probe molecules such as 1-pyrenecarboxylic acid [3443-45-6], perylene dibutyrate [79869-59-3] and 7-aminocoumarin dyes. Immobilized room temperature luminescent metal chelates, such as aluminum(III) 8-hydroxy-7-iodo-5-quinolinesulfonate, zirconium(IV) 8-hydroxy-7-iodo-5-quinolinesulfonate, platinum dimer tetras(pyrrophosphophitido)diplatin(II) and Ru(II) L₃²⁺ (L = 2, 2′-bipyridine, 1,10-phenanthroline and substituted derivatives) are also suitable probes for molecular oxygen sensors. In the latter set of applications reduction in measured fluorescent and/or phosphorescent signals is mathematically related to molecular oxygen concentration, Cₒxygen, through Stern–Volmer quenching Equation (9):

\[ \frac{F_0}{F_0} = K_{\text{Oxygen}}C_{\text{Oxygen}} \]  

(9)

where \( F_0 \) and \( F \) are the observed fluorescence intensity in the absence and presence of oxygen, respectively, and \( K \) is the quenching constant. Two-site Stern–Volmer models may be required at times to explain the quenching behavior of fluorophores immobilized in polymeric matrices. Microheterogeneity can cause the different solubilization sites to be quenched differently.

The newer chemical sensors are designed using fluorescent lifetime techniques. Analyte concentration is computed from the decay time of the fluorophore in contact with the sample being monitored. Lifetime-based chemical sensing is preferred over conventional intensity-based fluorescence methods because the measured lifetime is nearly independent of probe concentration. Lifetime measurements are thus unaffected by photobleaching or washout of the probe molecule. Probe molecules typically display lifetimes in the 1 to 10 nanosecond range. Molecular oxygen and ammonia have been detected based upon the spectral properties of select metal–ferron complexes and the sulforhodamine 101 [12333-78-8] and bromocresol purple mixed probe resonance energy transfer system, respectively. The preceding examples represent only a small fraction of the absorption and fluorescent probe-based chemical sensors that have been designed over the past two decades.

4 ULTRAVIOLET/VISIBLE ABSORPTION AND FLUORESCENT pH PROBES

Chemical sensors have been developed for pH determinations based upon both absorbance and fluorescence measurements. Probe molecules employed in the absorption-based sensors include common acid–base indicators such as neutral red, cresol red, phenol red, bromothymol blue, brilliant yellow, bromocresol green, bromocresol purple, chlorophenol red and bromophenol blue. Extensive tabulations of acid–base indicators, and their spectroscopically determined equilibrium dissociation constants, \( K_{\text{HIn}} \), have been published elsewhere. Dissociation of indicator results in a significant wavelength shift in the maximum absorption band, which is generally accompanied by a visual change in indicator color. Protonated and unprotonated forms of the indicator have different colors. Mathematically, the hydrogen ion concentration is related to the molar concentrations of acid (HIn) and base (In⁻) forms of the indicator probe molecule through the Henderson–Hasselbach Equation (10):

\[ \text{pH} = pK_{\text{HIn}} - \log \left( \frac{[\text{HIn}]}{[\text{In}^-]} \right) \]  

(10)

where \( pK_{\text{HIn}} \) refers to negative logarithm of the probe’s apparent acid dissociation constant. For convenience, activity coefficients have been incorporated in the dissociation constant. Measurements are performed at fixed probe concentration, and over a narrow interval of 1–2 pH units near pH ≈ \( pK_{\text{HIn}} \) a linear relationship between measured absorbance and solution pH is observed.

Mixed absorption probe systems have been used to extend the linear calibration curves by several pH units. Generally the indicator probes have approximately the same salt and same acid absorption spectrum (i.e. comparable wavelengths of maximum absorbance and nearly identical molar absorptivity ratios at the two wavelengths) with slightly different \( pK_a \) values. Concentrations are adjusted such that all probe molecules have the same measured absorbance in its salt (or acid) form at the analysis wavelength. Published studies have demonstrated that a linear absorbance versus pH calibration curve results whenever the differences in \( pK_a \)s between each successive pair of absorption pH probes is 1.6 pH units. The calibration curve for a mixed probe system is more linear and extends over a considerably larger range of hydrogen ion concentrations than does the corresponding curve for single probe systems. For example, the measured absorbance is reported to be linear from pH = 1.0 to pH = 7.0 for the mixed probe system containing 25.4 mg of neutral red + 10.2 mg of methyl red + 7.8 mg of methyl yellow + 14.1 mg of thymol blue. A second four probe system, with orange IV replacing thymol blue, exhibits a linear response up to pH = 8.

Fluorescence measurements also provide a convenient experimental means for pH determinations. In many applications involving chemical sensors, fluorescence-based measurements will be preferred to absorbance-based measurements because of their increased sensitivity,
greater latitude in geometric design, decreased background corrections, wider dynamic ranges, greater specificity through combined excitation–emission wavelength selection, and linear response at much lower spectroscopic probe concentrations. Generally, fluorescent pH probes are stronger acids in the excited state than in the ground state. For many pH probes fluorescence originates only from the excited state of the base form, and is observed at approximately 4–5 pH units below the ground-state pKₐ. A few indicators, such as 8-hydroxypyrene-1,3,6-trisulfonic acid, are fluorescent in both basic and acidic forms. Solution pH can be monitored using hydroxypyrenetrisulfonic acid probe by simply measuring relative intensities of the molecule’s basic and acidic forms, rather than by measuring the absolute intensity of the basic (or acidic) form. The calculated $F_{\text{base}}/F_{\text{acid}}$ intensity ratio provides an internal reference point, which eliminates the necessity for repeated calibrations.

Figure 2 depicts the variation in the observed emission intensity ratios of CF, DiMCF, BCECF and HMCo as a function of solution pH. Fluorescence is measured at a fixed emission wavelength. Different excitation wavelengths are needed to excite the protonated (i.e. $\lambda_{\text{ex}} = 334$ nm in HMCo) and anionic (i.e. $\lambda_{\text{ex}} = 365$ nm in HMCo) forms of the four pH probes. In the case of fluorescein derivatives the emission spectrum is dominated by the dianion, with only small contributions from monoanion (protonated phenol group). Both the phenol and carboxylic acid function groups of fluorescein are almost totally ionized in aqueous solutions above a pH of 9. Near linear calculated $F_{\text{base}}/F_{\text{acid}}$ versus pH calibration curves enable a fairly accurate determination of the hydrogen ion concentration over a 1–2 unit range of pH. Sensitivity of the analytical method is determined by difference between the quantum yields of fluorescent probe’s acid and base forms. For many of the recently published fluorescence methods, estimated uncertainty was reported to be ±0.01–0.1 pH units. Table 3 lists several of the common fluorescent pH probes, along with their applicable pH range and select spectral properties. The pH ranges that are given pertain to steady-state fluorescence measurements.

Three mixed indicator systems, containing both a pH-sensitive absorption probe and pH-sensitive fluorescent probe molecule, are also included in the tabulation. These particular systems were designed to provide greater sensitivity by compressing the entire observed spectral change into a much narrower range of hydrogen ion concentrations. The method is based upon primary and secondary inner-filtering effects. In a typical application, the fluorescent probe molecule would have low absorption at its excitation wavelength in acidic solutions. A weak fluorescent signal would be observed at low pH. An absorption probe molecule is added to the solution to overlap the fluorescent probe’s excitation spectrum. If necessary, a second absorption probe could be introduced to overlap with the emission spectrum as well. At low pH, the absorption probe has a high molar absorptivity. At the higher pHs, the fluorescent probe has a high absorption, whereas the absorption indicator is nearly optically transparent at both the excitation and emission wavelengths. Under these circumstances, the fluorescent probe’s emission signal is significantly reduced in solutions of low pH because of strong absorption of the incoming excitation radiation by the second indicator. Very slight reduction in emission signal occurs at the upper end of the pH range. The net effect of the added absorption indicator is to compress the entire observed fluorescence emission change into a much narrower range of hydrogen ion concentrations, thereby increasing the analytical method’s sensitivity.

SNARF and SNAFL derivatives have been used as probes in fluorescent lifetime-based pH determinations. Sensors containing the probes have employed phase-modulation fluorometry. Measured phase and modulation values depend upon both the excitation and emission wavelengths, as well as the hydrogen ion concentration. Through judicious wavelength selection, Szmacinski and Lakowicz demonstrated that a given...

5 FLUORESCENT WAVELENGTH-SHIFT SOLVENT POLARITY PROBES

Sufficient time exists between the excitation and emission process in fluorescence spectroscopy for physical re-orientation of solvational sphere molecules. Physical re-orientation occurs as solvent molecules move to align their respective dipole moments with the new dipole moment of the excited fluorophore. Alignment of fluorophore–solvent dipole moments leads to more effective molecular interactions, which is reflected in a lower excited state energy level relative to the ground electronic state. Energy lowering increases with increasing fluorophore–solvent interactions and solvent polarity as depicted in Figure 3.<sup>39</sup> Most fluorescent probes have a much larger excited state than ground state dipole moment, hence the energy level of the ground state is affected to a much lesser extent. As a general rule-of-thumb the larger redshifts in emission band wavelength(s) are observed in the more polar solvents. Emission wavelength(s) of fluorescent solvent polarity...
probe molecules provides a quantitative measure of the polarity of the solubilizing solvent media.

Theoretical interpretation of solvatochromic wavelength shifts at the molecular level is very difficult, often subject to interpretation, and as one may surmise there have been numerous competing mathematical expressions published in the spectroscopic literature to explain observed wavelength shifts associated with known solute probes. To a first approximation specific effects are ignored. The energy difference (in cm$^{-1}$) between solvated ground and excited state fluorophore can be described by the Lippert equation (Equation 11):\(^{(40)}\)

$$\frac{1}{\lambda_{ex}} - \frac{1}{\lambda_{em}} \approx \frac{2 (\mu^* - \mu)^2}{hc} \times \frac{\varepsilon - 1}{2\varepsilon + 1} - \frac{n^2 - 1}{2n^2 + 1} \text{ constant (11)}$$

or modified forms such as Equation (12):

$$\frac{1}{\lambda_{ex}} - \frac{1}{\lambda_{em}} \approx \frac{2 (\mu^* - \mu)^2}{hc} \times \frac{\varepsilon - 1}{2\varepsilon + 1} - \frac{\beta(n^2 - 1)}{(2n^2 + 1)} \text{ constant (12)}$$

where $\mu$ and $\mu^*$ refer to the ground state and excited state dipole moment, respectively, $\varepsilon$ and $n$ are the dielectric constant and refractive index of the solvent, $c$ is the speed of light, $h$ denotes Planck's constant, and $a$ is the radius of the solvent cavity wherein the fluorophore resides. Equations (11) and (12) both imply a linear relationship between the observed Stokes shift, $1/\lambda_{ex} - 1/\lambda_{em}$, and a specific function of the solvent’s refractive index and dielectric constant. The excited state dipole moment can be estimated through a linear least-squares regressional analysis of experimental Stokes shift data in accordance with Equation (11) (or 12).

Most fluorescent compounds do show some degree of solvatochromism as a result of molecular interactions with surrounding solvent molecules. The $(\mu^* - \mu)^2/a^3$ multiplicative factor in Equations (11) and (12) governs to a large extent the magnitude of the Stokes shift that the fluorophore experiences in going from a nonpolar to polar solubilizing medium. For fluorescent solvent polarity probes there generally is a nonpolar to polar solubilizing medium. For fluorescent solvent polarity probes there generally is a large difference between the ground and excited state dipole moments, which leads to sizeable shift in the excitation and/or emission wavelengths. Coumarin-153 \[53518-18-6\], 4-amino-N-methylphthalalimide \[2307-00-8\], 6-propionyl-2-(dimethylamino)naphthalene (PRODAN) \[70504-01-7\], 1-phenyl-4-(2-naphthylmethylene)piperidine (PNMP) \[91759-51-2\], 4-phenyl-4-(4-cyano-1-naphthylmethylene)piperidine (PCNMP) \[91759-53-3\] and the other compounds listed in Table 4 exhibit fairly large wavelength shifts in their recorded fluorescence spectrum as a function of solvent polarity. Each molecule listed has been recommended as a solvent polarity probe. Caution should be exercised in selecting a probe molecule for a particular application. Several molecules listed in Table 4 do contain acidic and/or basic functional groups; and as a result their spectral response may not necessarily be just to solvent polarity. Proton or charge transfer may contribute to the wavelength shift(s) for select solvents. Catalan et al.\(^{(53)}\) issued a similar precaution when using PRODAN as an indicator of the polarity of protein cavities, particularly if the environments being examined contain acidic sites. The authors had to introduce a new acidic term into the Lippert equation to satisfactorily explain the observed absorption and emission spectroscopic behavior of PRODAN in several solvents.

6 FLUORESCENT TWISTED INTRAMOLECULAR CHARGE TRANSFER PROBES

Solvatochromic probe character can also result from charge-transfer induced dual fluorescence. Molecular systems that are known to exhibit such behavior include 9,9’-bianthracene (BA) \[1055-23-8\], 4-((9-aryl)-N,N-dimethylaniline \[38474-09-8\], 4-(N,N-dimethylamino)benzonitrile \[1197-19-9\], ethyl 4-(N,N-dimethylamino)benzoate \[10287-53-3\] and N-arylcabazoles. Theoretical treatments often assume equilibrium between the locally excited (LE) and twisted intramolecular charge transfer (TICT) species, which for BA is represented as\(^{(54)}\) (Equation 13)

$$\text{An}^+ - \text{An}^- \quad \text{An} - \text{An}^* \quad \text{An}^+ - \text{An}^- \quad \text{TICT} \quad \text{LE} \quad \text{TICT}$$

with full electron/charge transfer separation. The two anthracene rings (denoted as An) twist to a perpendicular configuration to accommodate the separated charges. Fluorescence emission originates from LE and TICT excited states. The TICT band appears at longer wavelengths, and is more affected by solvent polarity/polarizability than is the LE band (see Figures 4 and 5). Emission band intensities are dictated by the fluorescent quantum yield and relative concentration of the two presumed isomeric species. More polar solvents like dimethyl sulfoxide favor the TICT species, and recorded emission spectrum in polar solvents often shows just the single TICT band. A bilinear Lippert relationship is generally seen in the case of TICT formation, with separate lines for each emission process.

$p$-Toluidonaphthalene sulfonate (TNS) is also listed as fluorescent TICT probe. In water, where the polarity is high, the TICT rates of TNS are very large and

**Figure 4**: Potential energy diagram showing the local excited and charge transfer state energies as a function of solvent polarity for a typical TICT compound. (Redrawn with permission from R.D. Schulte, J.F. Kauffman, *Appl. Spectrosc.*, 49, 31–39. Copyright (1995) Society for Applied Spectroscopy.)

the fluorescent quantum yield is very small, i.e. $\phi_f \approx 0.001$. The TICT process in the case of this particular fluorescent probe is nonradiative. When TNS binds to the nonpolar, hydrophobic surfaces of micelles, proteins or apolar CD cavities, the TICT process is inhibited. This causes a dramatic increase in the fluorescent quantum yield. The fluorescence intensity enhancement

**Figure 5**: Corrected fluorescence spectra (room temperature) of BA, 10-chloro-9,9’-bianthracene (BACl) and N-($p$-anthryl)-carbazole (C9A) in nonpolar and polar aprotic solvents: hexane (-----), ethyl ether (- - - -), tetrahydrofuran (••••••••••) and acetonitrile (••••••••••). (Redrawn with permission from W. Rettig and M. Zander, *Ber. Bunsen-Ges. Phys. Chem.*, 87, 1143–1149. Copyright 1983 Wiley-VCH.)
thus provides direct information about polarity of the microenvironment in the immediate vicinity of the TNS probe molecule.

The following examples illustrate the type of information that can be obtained with TICT probe molecules. Kajimoto and coworkers\(^{(55)}\) used fluorescence emission from the TICT state of 4-(N,N-dimethylamino)benzonitrile to investigate solvent structure in the cybotactic region of supercritical trifluoromethane. Experimental measurements revealed that both the Stokes shift and calculated \(\frac{F_{\text{TICT}}}{F_{\text{LE}}}\) emission intensity ratio increased with increasing fluid density. Observed spectral wavelength shifts were compared to values predicted from theoretical models that assume a homogeneous dielectric solvent. Analysis of the experimental data indicated that near the critical point the local solvent density around the probe molecule was greater than the bulk solvent. The CHF\(_3\) solvent molecules were not uniformly dispersed, but rather tended to aggregate around the fluorophore. At low densities, the number of solvent molecules within the fluorophore’s solvational sphere depended linearly upon the bulk solvent density. More recently, TICT probes 4-(N,N-dimethylamino)benzonitrile and ethyl 4-(N,N-dimethylamino)benzoate were used to study interactions in supercritical trifluoromethane and carbon dioxide at different solvent compositions.\(^{(56)}\)

TICT probes can examine structural features inside CD cavities. The most widely used CD molecules contain six, seven and eight glucose monomers arranged in toris shapes, and are named \(\alpha\), \(\beta\)- and \(\gamma\)-CD, respectively. Coupling of the glucose molecules gives the CD a rigid, conical molecular structure with a hollow hydrophobic interior that enables the CDs to trap probe molecules based upon molecular shape/size compatibility. \(\gamma\)-CD is the larger of the commercially available CDs, having an internal diameter of approximately 9.5 Å and depth of roughly 7.8 Å. Published fluorescence measurements indicate that LE and TICT electronic states of 4-(N,N-dimethylamino)benzonitrile form 1:1 guest–host inclusion complexes with \(\beta\)-CD. The two electronic states reside in different microenvironments within the cavity.\(^{(57)}\)

7 FLUORESCENT POLYCYCLIC AROMATIC HYDROCARBON SOLVENT POLARITY PROBES

Pertinent photophysical processes governing fluorescence behavior of polycyclic aromatic hydrocarbons (PAHs) dissolved in fluid solution are summarized below:

\[
\begin{align*}
\text{PAH} + h\nu_0 & \rightarrow \text{PAH}^* \quad \text{(absorption/excitation)} \\
\text{PAH}^* & \rightarrow \text{PAH} + h\nu_1 \quad \text{(emission)} \\
\text{PAH}^* + \text{PAH} & \rightarrow (\text{PAH})_2^* \quad \text{(excimer formation)} \\
(\text{PAH})_2^* & \rightarrow 2\text{PAH} + h\nu_2 \quad \text{(excimer emission)}
\end{align*}
\]

Emission spectrum of PAH monomer consists of several major vibronic bands labeled I, II, III, etc., in progressive order, starting with the O–O vibronic band. Published studies\(^{(58–60)}\) revealed that Py, benzo[ghi]perylene (BPe)\(^{[191-24-2]}\), ovalene (Ov)\(^{[190-26-1]}\), coronene (Co)\(^{[191-07-1]}\), benzo[a]coronene (BCo)\(^{[190-7-5]}\), naphtho[2,3,a]coronene (NCo)\(^{[190-74-9]}\), dibenzo[a,j]coronene (DCo)\(^{[190-72-7]}\), benzo[cd]pyrene (BePy)\(^{[192-97-2]}\), 3,4-dihydrobenzo[ghi]perylen (DHBPe)\(^{[16310-65-9]}\), benzo[rsr]pentaphene (BPP)\(^{[189-55-9]}\), methylcoronene (MeCo)\(^{[13119-86-3]}\), 1,2-dimethylcoronene (DiMeCo)\(^{[113523-79-8]}\) and several other PAHs exhibit selective emission intensity of vibronic band I relative to band III (or band IV) in polar solvents (see Figure 6). Ratios of band I and III (or IV) serve as quantitative measure of solvent polarity and structure. Less than 25% of the PAH solutes studied to date exhibit probe character. Emission intensity ratios for the majority of PAHs remain essentially constant, irrespective of solvent polarity.

Tables 5 and 6 list experimental emission intensity ratios for Py, BPe, Co, BePy, DHBPe, Ov, MeCo and DiMeCo dissolved in select nonelectrolyte solvents. Careful examination of the entries in Table 7 reveals that, for the most part, the rank ordering of solvents by polarity is identical for the eight PAH probes. Linear least-squares analysis of the intensity ratio data shows that the polarity scales are highly correlated as indicated by the squared correlation coefficient, \(r^2\).

Of the known PAHs that exhibit selective emission intensity enhancement, the eight molecules listed above are the ones recommended for solvent polarity...

<sup>a</sup> Experimental Py values are taken in part from Dong and Winnik<sup>58</sup> and are based upon the properties of Py.
<sup>b</sup> Defined as the ratio of band I (405 nm)/band III (417 nm) for benzo[ghi]perylene.
<sup>c</sup> Defined as the ratio of band I (424 nm)/band III (445 nm) for Co.
<sup>d</sup> Defined as the ratio of band I (480–485 nm)/band III (500–505 nm) for Ov.

determinations. The eight PAHs have various shapes and different excitation wavelength(s). Depending upon the spectral characteristics of the organic solvent and/or molecular shape/size constraints imposed by the organized solvent media being examined, one PAH probe may be preferred from an experimental standpoint.

Py solvent polarity scale is defined as the $F_1/F_3$ emission intensity ratio, where band I corresponds to $S_1(v = 0) → S_0(v = 0)$ transition and band III is a $S_1(v = 0) → S_0(v = 1)$ transition. Karpovich and Blanchard<sup>61</sup> rationalized Py’s solvatochromic behavior in terms of vibronic coupling between the weakly allowed Py first electronic excited singlet state ($\epsilon_{\text{max}} \approx 200 \text{ cm}^{-1} \text{ M}^{-1}$) and the strongly allowed second electronic singlet state. The observed Py absorption/excitation spectrum involves $S_0 → S_2$ electronic transition. The nonprobe perylene molecule, on the other hand, exhibits the typical excitation–emission mirror image symmetry common to many PAHs. Perylene absorption/excitation spectrum corresponds to the ground state $→$ first electronic excited state transition ($\epsilon_{\text{max}} \approx 33,000 \text{ cm}^{-1} \text{ M}^{-1}$ for $S_0 → S_1$).

Vibrationally mediated coupling between electronic $S_1$ and $S_2$ states can be mathematically described through both Herzberg–Teller (HT) and Born–Oppenheimer (BO) contributions. Equations derived by Karpovich and Blanchard indicate that the magnitude of nuclear displacement along the coupling coordinate is sensitive to the dipolar and dielectric properties of surrounding solvent media. Vibronic coupling contributions to the O–O absorption and emission cross-sections scale as HT + BO and HT – BO contributions, respectively. For a two level system, such as the O–O Py transition, cross-sections for the absorption and emission processes must be equal. Hence, (HT + BO)$_{O→O}$ = (HT – BO)$_{O→O}$, and I band intensity depends solely upon the HT coupling between $S_2$ and $S_1$ electronic states. Band III corresponds to a $S_1(v = 0) → S_0(v = 1)$ electronic transition, with its emission intensity being determined by the difference between

the HT and BO contributions. This difference is less solvent dependent than each of the separate HT and BO contributions. The \(F_1/F_3\) emission intensity ratio thus increases with increasing solvent polarity.

Fluorescent PAH solvent polarity probes have been used in applications ranging from the determination of critical micelle concentrations, to measurement of solvent polarity of gas–liquid chromatographic (GLC) and HPLC stationary phases to estimation of preferential solvation in binary solvent mixtures. In this latter application, most published approaches assume that a given fluorophore’s solvational sphere contains just solvent molecules A. Other fluorophore molecules in the solution would be solvated completed by solvent component B. Each solvated fluorophore contributes to the observed fluorescence signal, \(F_{\text{obs}}\), at each emission wavelength scanned. Emission intensities are additive at each wavelength. In the case of a PAH probe such as Py, the calculated \(F_1/F_3\) emission intensity ratio is\(^{62}\) given by the Equation (14):

\[
\frac{F_1}{F_3} \approx \left[ Y_A F_{1,\text{phase A}} + (1 - Y_A) F_{1,\text{phase B}} \right] + \left[ Y_A F_{3,\text{phase A}} + (1 - Y_A) F_{3,\text{phase B}} \right]
\]

Here, [Fluoro] is the total stoichiometric fluorophore molar concentration, and \(Y_A\) and \(1 - Y_A\) represent the mole number fraction of each type of solvated fluorophore, i.e. \(Y_A = [\text{Fluoro A}] / [\text{Fluoro}]\) and \((1 - Y_A) = [\text{Fluoro B}] / [\text{Fluoro}]\). Solute concentration must be
maintained constant for all fluorescence measurements. Equation (14) does accurately reproduce fluorescence behavior of Py, DHBPe, Co and BePy dissolved in n-heptane + 1,4-dioxane and n-heptane + tetrahydrofuran mixtures. Calculated \( Y_A \) values indicated that the PAH solute probe was preferentially solvated by the nonpolar n-heptane cosolvent, with the degree of preferential solvation decreasing with increased PAH molecular size.\(^{62}\)

Modified forms of the general spectral response equation have been used successfully in the calculation of equilibrium constants for PAH–CD complex formation, and in the calculation of binding constants for PAH–surfactant complexation. As a classical example, Xu et al.\(^{63}\) examined interactions between Py and \( \alpha \)- and \( \beta \)-CD and/or polymerically linked \( \beta \)-CDs. Experimental fluorescence emission intensity versus CD concentration curves were analyzed in terms of four existing literature models. Of the models considered only the one assuming sequential formation of 1:1 and 1:2 Py–CD complexes, with each complex being fluorescent and having different \( F_1/F_3 \) emission intensity ratios, was found to describe the monomeric CD data satisfactorily. At each emission wavelength scanned, the observed fluorescence signal, \( F_{\text{obs}} \), is the sum of the emission intensities from the Py monomer and two fluorescent Py–CD complexes. The measured I and III band emission intensities are given by Equations (15) and (16):

\[
\begin{align*}
F_1 &= f_{\text{Py}} F_{1,\text{Py}} + f_{\text{Py–CD}} F_{1,\text{Py–CD}} \\
&\quad + f_{\text{CD–Py–CD}} F_{1,\text{CD–Py–CD}} \\
F_3 &= f_{\text{Py}} F_{3,\text{Py}} + f_{\text{Py–CD}} F_{3,\text{Py–CD}} \\
&\quad + f_{\text{CD–Py–CD}} F_{3,\text{CD–Py–CD}}
\end{align*}
\]

where \( f \) is the fraction of Py existing as the uncomplexed Py, 1:1 and 1:2 Py–CD complexes. The four emission intensities involving the Py–CD complexes cannot be experimentally determined because each PAH–CD complex must be in equilibrium with the uncomplexed PAH monomer. To circumvent this problem, Equation (15) is recast as Equation (17):

\[
F_1 = f_{\text{Py}} \left( \frac{F_1}{F_3} \right)_p y F_{3,\text{Py}} + f_{\text{Py–CD}} \left( \frac{F_1}{F_3} \right)_{\text{Py–CD}} F_{3,\text{Py–CD}} \\
+ f_{\text{CD–Py–CD}} \left( \frac{F_1}{F_3} \right)_{\text{CD–Py–CD}} F_{3,\text{CD–Py–CD}}
\]

using \( F_1/F_3 \) emission intensity ratios, equilibrium constants and \( F_3 \) values which scale the calculation to the observed data. The various fractions were expressed in terms of the two equilibrium constants, uncomplexed Py and CD concentrations. Through a global fitting of \( F_1 \) and \( F_3 \) data simultaneously, optimized numerical values of the equilibrium constants were calculated.

The number of required input parameters (e.g. fluorescence emission properties) is reduced through simplifying approximations. Examination of Equation (14) reveals that the measured \( F_1/F_3 \) emission intensity ratio for a PAH probe dissolved in a binary solvent mixture (or alternatively, for a PAH probe dissolved in two different microenvironments) becomes Equation (18):

\[
\frac{F_1}{F_3} = Y_A \left( \frac{F_1}{F_3} \right)_{\text{phase A}} + (1 - Y_A) \left( \frac{F_1}{F_3} \right)_{\text{phase B}}
\]

a weighted average of the measured emission intensity ratios in each pure solvent, \( (F_1/F_3)_{\text{phase A}} \) and \( (F_1/F_3)_{\text{phase B}} \), provided that probe’s measured III band intensity is identical in both neat solvents (or microenvironments/phases). Equation (18) requires knowledge of only the \( F_1/F_3 \) emission intensity ratio for each different solvational species, rather than individual emission intensities at two different wavelengths. This reduces the number of input parameters by a factor of two, and eliminates in part experimental artifacts that might result from each solution having a slightly different analytical concentration of the dissolved PAH probe molecule. Recent studies addressed influences that chiral modifiers, diols and amines have in regards to Py–CD complexation. Complexation between Py and derivatized-CDs and between Py and cationic surfactant headgroups have been studied by fluorescence probe methods, several of which were based upon Equation (18).

8 FLUORESCENT ANISOTROPIC AND MICROVISCOITY PROBES

Fluorescence anisotropic measurements provide valuable information in regards to the fluorophore’s orientational and rotational motions. Anisotropy is an angular correlation function that describes the mutual orientation of both the absorption and emission transition dipole moments at the times of excitation (\( t = 0 \)) and emission (\( t = \tau \)). Fluorophores whose absorption dipoles are aligned with the electric vector of the excitation radiation have the highest probability of excitation when irradiated with polarized light. Photoselection rules dictate that the resulting fluorescence must also be polarized. Fluorescence does not occur immediately. There is sufficient time for the fluorophore to rotate during the excited state lifetime. Some depolarization occurs as a result of rotational motion. The magnitude of the depolarization depends upon the fluorophore’s molecular size and shape, as well as upon the viscosity of the microenvironment in the fluorophore’s immediate vicinity. Fluorescence
polarization measurements have been used to investigate ligand binding, protein denaturation and surfactant aggregation.

In steady-state fluorescence anisotropic studies, spectra are acquired by scanning wavelengths selected by an excitation monochromator, and then measuring the emission intensity parallel, \( F_\parallel \), and perpendicular, \( F_\perp \), to the polarization of the excitation radiation. Mathematically, the degree of polarization and the anisotropy are defined by Equations (19) and (20):

\[
P = \frac{F_\parallel - F_\perp}{F_\parallel + F_\perp} \quad (19)
\]

\[
r = \frac{F_\parallel - F_\perp}{F_\parallel + 2F_\perp} \quad (20)
\]

The above definitions also hold for time-resolved fluorescence measurements. Emission intensities would now be time-dependent functions, \( F_\parallel(t) \) and \( F_\perp(t) \), as opposed to an actual numerical value. Correction terms can be added to eliminate effects from stray radiation.

It can be shown that the initial (\( t = 0 \)) and maximum value of the anisotropy, \( r_0 \), is 2/5 for any macroscopically isotropic orientational distribution of fluorophore molecules. This is of course the theoretical limiting value that one expects to observe in systems where rotational motions become negligible. The limiting value is never observed, however, not even in systems where the temperature has been lowered to restrict rotational motions. The smaller experimental \( r_0 \) values have been explained in terms of torsional vibrations of the fluorescent molecules about their equilibrium orientation, combined with perhaps a small rotation of the absorption and emission dipoles due to coupling with vibrational modes. Since the theoretical value is never realized, the operational definition of the limiting fluorescence anisotropy is the maximum value that is experimentally measured.

Popular fluorescent anisotropic probe molecules include: perylene [198-55-0], PRODAN, 1,4-diphénylbuta-1,3-diene [886-65-7], 1,6-diphenylhexa-1,3,5-triene [1720-32-7], anthracene [120-12-7], 2-methylanthracene [613-12-7], 9-vinylanthracene [2444-68-0], potassium 2-(p-toluidino)naphthalene-6-sulfonate [32752-10-6], rhodamine B [81-88-9], rhodamine 6G [989-38-8], rhodamine 101 [41175-43-3], fluorescein [2321-07-5], 2,5,8,11-tetra-tert-butylperylene (TBP) [80663-92-9] and 9-(3-perylenoyl)nonanoic acid. Spectral properties of selected probes are listed in Table 8. Each molecule contains a fluorescent moiety. Functional groups are added to modify the molecule’s rotational motion and to provide a means of judiciously controlling location of the probe within a molecularly-organized, biological and/or membrane system. Polar and ionic functional groups increase the probe’s aqueous solubility.

Fluorescent anisotropic probe methods provide a convenient experimental technique for determining microviscosity of molecularly-organized structures. If rotational diffusion is the main cause of anisotropy loss, then observed anisotropy is related to the microviscosity, \( \eta \), by the Perrin equation (Equation 21):

\[
r = \frac{r_0}{1 + (\pi kT/\eta V)} \quad (21)
\]

where \( k \) is the Boltzmann constant, \( T \) denotes the absolute Kelvin temperature, and \( V \) and \( \tau \) refer to the effective molecular volume and fluorescence lifetime of the probe, respectively. Equation (21) applies to a spherical rotor, and in several published applications \( V \) was assumed to have a functional dependence upon \( r \). Calibration curves of measured \( r_0/r \) values versus known \( \tau V/\eta \) values are available for several probes.\(^{60}\) More complex expressions have been derived for nonsymmetric species or molecules.

Microviscosities have been estimated using ratio of intramolecular excimer to monomer fluorescence emission intensities (i.e. \( F_{\text{excimer}}/F_{\text{monomer}} \)). The method involves construction of a calibration curve by measuring \( F_{\text{excimer}}/F_{\text{monomer}} \) ratios in solutions of known viscosity since there is no theoretical relationship for how the emission intensity ratio should vary with \( \eta \). As a cautionary note, calibration curves should be established under isothermal experimental conditions. Excimer formation is affected by temperature, and changes in measured \( F_{\text{excimer}}/F_{\text{monomer}} \) ratio forms the basis for fluorescent thermometer development. 1,3-Di(\( \alpha \)-naphthyl)propane \(^{78,79}\) [14564-86-4] and bis(4-biphenylmethyl)ether \(^{80}\) [68941-68-4] are recommended probe molecules for the \( F_{\text{excimer}}/F_{\text{monomer}} \) method. Microviscosity determinations using intermolecular excimer formation are generally not as effective, particularly in molecularly organized solvent structures such as micelles. It is much easier to control micellar fluorophore distribution leading to excimer formation whenever the two chromophoric moieties are contained within the same molecule.

Perylene initially was identified as an anisotropic rotator in steady-state polarization measurements. Wavelength-dependent Perrin plots indicated the presence of at least two rotational motions, which were confirmed by subsequent time-resolved fluorescence techniques. Rate of rotation of perylene about its major symmetry axis (\( z \)-axis) is an order of magnitude greater than the rate of rotation perpendicular to the \( z \)-axis. Time-resolved fluorescence anisotropies of perylene are generally characterized by a double-exponential model. Calculated rotational decay times can be related to the diffusion about the in-plane and out-of-plane molecular axis.
Rotational decays become equal, however, if four tert-butyl groups are substituted symmetrically into perylene. Anisotropy decay of TBP is monoexponential. The following representative examples illustrate the type of information that anisotropic probes can provide. Jobe and Verrall\(^\text{64}\) employed polarized fluorescence emission to determine microviscosity of ternary mixtures containing 2-butoxyethanol, cetyltrimethylammonium bromide (CTAB) and water. Diphenylbutadiene was used as anisotropic probe molecule. Strong columbic binding prevented the authors from using potassium 2-
(p-toluidino)naphthalene-6-sulfonate. At fixed surfactant concentration, the microviscosity was found to decrease with increasing 2-butoxyethanol concentration. The polar alkoxyalcohol effectively penetrated into the palisade region causing the CTAB micelle to swell. As part of the investigation the microviscosity of aqueous CTAB, sodium dodecyl sulfate (SDS), tetradecytrimethylammonium bromide (TTAB) and cetylpyridinium bromide (CTPB) were also determined. Calculated values ranged from \(\eta \approx 14\) cP to \(\eta \approx 29\) cP, and were in excellent agreement with published values based upon the polarized fluorescence behavior of anthracene and 2-methylnaphthalene.

Betts et al.\(^\text{72}\) estimated solute–fluid cluster sizes in supercritical \(\text{N}_2\text{O}\) based upon the measured fluorescence anisotropic and lifetime data for the probe molecule PRODAN. Measured steady-state anisotropies in supercritical \(\text{N}_2\text{O}\) decreased with increasing pressure, whereas in liquid \(\text{N}_2\text{O}\) the observed anisotropy remained essentially constant. Two limiting cases were considered. In the first case, the authors assumed only minimal interaction between the probe PRODAN and surrounding \(\text{N}_2\text{O}\) solvent molecules. The probe was free to rotate within the locally enriched solvent cluster environment. Strong probe–solvent interactions were assumed in the second model. Probe plus cluster was now treated as a single rotating body. Analysis of experimental data within this framework yielded an average cluster size containing

between 25 and 103 N₂O molecules near the critical pressure.

More recently, time-resolved anisotropic measurements have been utilized to examine rotational reorientation dynamics of Aerosol-OT reverse micelles formed in near-critical propane solvent. Cationic anisotro-

pic probes rhodamine 6G and rhodamine 101 were solubilized within the reverse micelle. Experimental data were interpreted using a bi-exponential rate law expression, with the rotational correlation times describing both the independent lateral rotation diffusion of the fluo-

rophore along the water–headgroup interfacial region within the reverse micelle and the global rotational motion of the entire micelle. Rotational correlation times for the micelle were 40 times slower than expected, and suggested the formation of micelle–micelle aggregates. The study complemented the authors’ earlier work involving rotational motion of several xanthene dyes (rhodamine 6G, rhodamine B, rhodamine 101 and fluorescein). Here, probes were solubilized in Aerosol-OT reverse micelles formed in heptane.

9 FLUORESCENT TEMPERATURE PROBES

Fluorescence-based temperature sensing is becoming increasingly more popular for monitoring processes occurring in microscopic and hostile environments where conventional thermometry is either impractical or impossible. Temperature-sensitive fluorescent probes provide a relatively noninvasive method to study biological cells. Published applications include temperature measurement in evaporating fuel sprays and burning flames, examination of temperature fluctuations on surfaces of turbine engines and monitoring dynamic heat transfer in chemical reactions. In each application, a systematic change was observed in spectral properties of the probe molecule with increasing/decreasing temperature. Observed spectral changes were generally manifested as either shifts in the emission wavelength(s) or variations in measured intensities of selected emission bands caused by thermal excitation of vibronic states in the electronic excited state (i.e. fluorescence hot-band emission), changes in the microenvironment’s refractive index and dielectric constant, or by differences in the monomer/excimer (or monomer/exciplex) concentration ratio in systems where excimer (or exciplex) formation occurs.

Accurate temperature determination requires that measured fluorescence spectra be free of inherent fluctuations in the intensity of the excitation radiation source and other instrumental artifacts. Strategies that have proved successful in this regard have involved the design of probe molecules having two fluorescent moieties or the utilization of molecules that exhibit an emission intensity enhancement of select vibronic bands. The emission intensity of the non-enhanced band(s) would serve as an internal reference point, thus reducing the problems associated with measurements based upon a single emission process.

Of the probe molecules that have been suggested as fluorescent thermometers, N-(1-pyrenylmethyl)-1-

pyrenebutamide (PMPBA) [187589-23-7] and N-(1-pyre-

nylethyl)-1-pyreneacetamide (PMPAA) [187589-24-8] are perhaps the most versatile for applications between ambient room temperature and 100 °C. The two pyrenyl fluorophoric centers give each molecule a high quantum yield and good sensitivity. As shown in Figure 7 the intramolecular excimer emission (which is centered around λem ≈ 448 nm in the case of PMPBA) decreases with increasing temperature. Normalization of excimer emission signals to those of the monomer eliminates the effects caused by excitation source fluctuations and variations in fluorophore concentrations and optical pathlength. Measured natural logarithm of $F_{\text{excimer}}/F_{\text{monomer}}$ emission intensity ratio versus reciprocal of the absolute Kelvin temperature, $1/T$, is nearly linear over the entire recommended temperature range. Lou et al. estimated the precision of temperature measurement to be within $\Delta T = \pm 0.7^\circ C$ and $\Delta T = \pm 0.8^\circ C$ for PMPBA and PMPAA, respectively (see Figure 8). 1,3-Bis-(1'-pyrenyl)propane (PyPyP) [61549-24-4] and 3-(4'-dimethylaminophenyl)-1-(1'-pyrenyl)propane (PyDMAP) [38764-41-9] can be used for measuring temperatures above 100 °C. The latter two molecules also exhibit temperature-dependent 

![Figure 7 Observed fluorescence emission spectra of 0.33 µM PMPBA dissolved in dodecane as a function of temperature. Spectra have been normalized to the intensity of the monomer band, which occurs at about 396 nm. (Redrawn from J. Lou, T.A. Hatton, P.E. Laibinis, Anal. Chem., 69, 1262–1264. Copyright (1997) American Chemical Society.)](image-url)
Fluorescent thermometers have been developed for measuring flame temperatures using anomalous $S_0 \leftrightarrow S_2$ fluorescence emission of isolated Py molecules.\(^\text{85–87}\) Emission intensity ratio for the $S_0 \leftrightarrow S_2$ and $S_0 \leftrightarrow S_1$ spectral transitions is known to depend strongly upon both excitation and temperature. At low temperatures (425–625 K) and pressures (less than 50 torr) fluorescence emission is related directly to the internal vibrational temperature of the Py molecules. A plot of logarithm of $S_2/S_1$ emission intensity ratio versus the reciprocal of absolute Kelvin temperature is linear over the 425–625 K temperature region. Py is an organic molecule and it does undergo chemical reactions in the more oxidative flames, which limit its applicability to nonoxidative environments. Suggested systems that could be monitored with a Py probe molecule include high-temperature exhausts, diffusion flames and nonreactive flows of interest in heat transfer and fluid mechanics.

In recent years temperature measurements have also been performed with fluorescent probes that exhibit systematic shifts in emission wavelengths with temperature. Extreme caution should be exercised in using this type of probe molecule since it has not yet been conclusively established that the observed emission wavelength response depends solely upon temperature. Changes in solvent properties also contribute to the observed fluorescent behavior as discussed in the section devoted to fluorescent solvent polarity probes. It is quite conceivable that changes in the solvent’s refractive index and/or dielectric constant may have contributed in part to observed probe character. Both dielectric constant and refractive index are temperature-dependent, and calibration curves established in one solvent media might not be transferable to another solvent media or molecularly organized system. Until this point is satisfactorily addressed it is recommended that the calibration curve relating the observed emission wavelength and temperature be made in a solvent whose physical properties closely mimic those of the intended application. This should help in minimizing any affects arising from changes in solvent properties brought about by temperature change.

FAR-VISIBLE AND NEAR-INFRARED ABSORPTION AND LUMINESCENT PROBES

Far-VIS and near-infrared absorption and luminescent probes\(^\text{88,89}\) are currently used in biological and medical applications as in vivo sensors/tracers. Few biologically active molecules absorb in the 600–1000 nm spectral region, and attachment of a near-infrared probe molecule
provides a means to label the analyte molecule of interest. Near-infrared probes typically possess large molar absorptivities (ε ≈ 200,000 cm⁻¹ M⁻¹) and reasonably good quantum yields (Φ_F ≈ 0.8), which facilitate spectrophotometric detection. Detection limit depends entirely upon spectral characteristics of the probe molecule and instrumentation capability. Background corrections for sample absorbance and/or fluorescence are negligible.

Molecules that exhibit long-wavelength absorption and emission generally have extensive delocalized double-bond conjugation. Two major families of molecules known to have long-wavelength absorption maxi ma are polymethine cyanine and phthalocyanine dyes. These dyes are practically insoluble in nonpolar organic solvents because of their ionic character; however, they do dissolve in most polar organic solvents and binary aqueous–organic mixtures. Polar and ionic functional groups can be added to judiciously alter molecules’ spectral properties and water solubility, or to provide a site for analyte attachment. Attachment involves either noncovalent binding or covalent bonding as in the case of a biological molecule, or complexation to a metal ion. For example, water solubility can be enhanced by the presence of a sulfonate group, whereas an added isothiocyanate group would allow the probe molecule to be selectively attached to the amino groups of proteins. Thiourea bond that would be formed is quite stable above a pH of 6.0. Several near-infrared probes are listed in Table 9, along with their spectral properties.

Far-VIS and near-infrared absorbing dyes have only recently been introduced into analytical chemistry, and their applications as spectroscopic probes have not yet been fully realized. Patonay and coworkers explored the feasibility of using polymethine cyanine dyes as solvent polarity probes, based upon their aggregation tendency in binary aqueous–alcohol mixtures. Of the four dyes studied, only IR-144 [54849-69-3] and BTPHB showed any real noticeable spectral change with solvent composition. The effect was more dramatic for BTPHB in that over a 110 nm shift was observed in the absorption spectra containing two peaks at intermediate solvent compositions as shown in Figure 9. Peaks were well-resolved and required no deconvolution to accurately quantify. The peak at 698 nm was attributed to formation of dimers (or perhaps higher associated aggregates). The authors suggested that the calculated Amonomer/(Amonomer + Adimer) absorbance ratio could serve as a useful measure of solvent hydrophobicity. Previously, it had been reported that the fluorescent lifetime of the polymethine dye 3,3’-diethyl-2,2’-(4,5:4’,5’-dibenzo)dithiatricarbocyanine iodide (NK-427) [20682-18-2] was highly correlated with solvent dielectric constant. Further experimental research is needed.

however, to firmly establish the BTPHB and NK-427 scales as meaningful measures of solvent hydrophobicity.

To date, less than a dozen near-infrared dyes have been used as probe molecules in actual pH measurements. Published examples include pH determinations based upon measured emission intensities of three immobilized tetra-substituted chloroaluminum 2,3-naphthocyanine dyes (functional groups were (5-NC)₄, (5-O₂N)₄ and (5-HOOC)₄) and a bis(carboxylic acid) derivative of 2-[4'-Chloro-7-(3'-ethyl-2''-benzothiazolinylidenyl)-3',5'-[1''',3''''-propanediyl]-1',3',5'-heptatriene-1'-yl]-3-ethylbenzothiazolium bromide, and upon hydrogen ion-induced changes in absorption spectra of aminodienone-carbocyanine dye system. In the latter example, spectral change resulted from keto–enol tautomerism caused by protonation of oxygen atom. Generally, such spectral changes occur over a fairly narrow pH range of less than 2–3 pH units. Finally several far-VIS and near-infrared spectroscopic probes such as porphines, isoporphines and corroles, as well as select cyclic derivatives of phthalocyanines and naphthalocyanines, have served as complexing agents for metal ions. Specificity of probe for various metal ions in solution is determined by both ring size and analyte’s affinity for the lone electron pairs on nitrogen ring atoms. Additional analytical applications will likely result in the next few years. New synthetic procedures are making probe molecules more readily available.

Circular dichroism (CD) is the difference in absorption, A, of left and right circularly polarized light, Equation (1):

\[ CD = \Delta A = A_l - A_r \] (1)

For randomly oriented systems such as solutions of molecules, only chiral molecules will show any CD intensity corresponding to their absorption bands. Chiral molecules are those molecules that cannot be superposed on their mirror images (1). Chiral is derived from the Greek word χειρ meaning hand, hence the alternate term for chirality, “handedness”. Two molecules that are mirror images of each other are often referred to as enantiomers and equimolar mixtures of two enantiomers form a racemic mixture which has no net CD intensity in solution.

Linear dichroism (LD) is the difference in absorption of light linearly polarized parallel and perpendicular to an orientation axis, Equation (68):

\[ LD = A_\parallel - A_\perp \] (68)

1 INTRODUCTION TO CIRCULAR DICHROISM

CD is the difference in absorption, A, of left and right circularly polarized light, Equation (1):

\[ CD = \Delta A = A_l - A_r \] (1)

For randomly oriented systems such as solutions of molecules, only chiral molecules will show any CD intensity corresponding to their absorption bands. Chiral molecules are those molecules that cannot be superposed on their mirror images. (1) Chiral is derived from the Greek word χειρ meaning hand, hence the alternate term for chirality, “handedness”. Two molecules that are mirror images of each other are often referred to as enantiomers and equimolar mixtures of two enantiomers form a racemic mixture which has no net CD intensity in solution (Figure 1).

In order to understand when chirality is important it is helpful to consider the everyday problem of a pair of shoes, a left foot, and a shoe box. The shoes and the foot are chiral and the left foot only fits comfortably into the left shoe, whereas the achiral shoe box cannot distinguish between the two shoes. Chirality is important only where two chiral entities (usually molecules) interact. CD depends only on the asymmetry of the molecular system and so is uniquely sensitive to this aspect of it. As many of the questions we ask about chemical and
biological systems relate to the shapes of molecules and how this affects their properties, CD is a very useful tool for studying chiral molecules.

CD is now a routine tool in many laboratories. The most common applications are determining whether a chiral molecule has been synthesized or resolved into pure enantiomers and probing the structure of biological macromolecules, in particular determining the $\alpha$-helical content of proteins.

1.1 Circularly Polarized Light

Although in principle CD can be measured for any kind of electromagnetic radiation absorbed by a sample, in practice experiments are usually limited to the visible or the easily accessible ultraviolet (UV) wavelength range (~170–800 nm). We often loosely refer to this electromagnetic radiation as “light”. Vibrational circular dichroism (VCD) using infrared radiation is also used, but is technically significantly more challenging. We shall concentrate on the ultraviolet/visible (UV/VIS) CD as this instrumentation is more readily available and significantly more widely used than VCD.

Electromagnetic radiation, as its name implies, has an electric and a magnetic field that oscillate at right angles to one another and to the propagation direction (Figure 2). Light may be described by a transverse wave whose polarization is defined by the direction of its electric field, $E$. Electromagnetic radiation also has particle character: if we do an experiment that would probe wave-like behavior, it is apparent that light has it, and if we look for particle character we find that too. Thus we refer to the wavelength, $\lambda$, and frequency, $v$, of radiation, but acknowledge that if a molecule absorbs energy it absorbs discrete units called photons whose energy are given by Planck’s relationship,

$$E = hv = \frac{h\nu}{2\pi} = h\nu$$

where $h$ is Planck’s constant and $\nu$ is known as the angular frequency. It follows from the wave nature of light that a light beam can be linearly polarized with all photons having their electric field oscillating in the same plane (Figure 2). In a circularly polarized light beam the electric field vector retains constant magnitude.
in time but traces out a helix about the propagation direction. Following the optics convention\(^{6–8}\) we take the end of the electric field vector of right circularly polarized light to form a right-handed helix in space at any instant of time. At each point in space or time, the magnetic field, \(B\), is perpendicular to the electric field such that \(k\), the propagation direction, \(E\), and \(B\) form a right-handed system as illustrated in Figure 2.

If we take \(X\) to be the direction of propagation of the light, then unit vectors describing the polarization (by convention the direction of the electric field component of the light) of two perpendicularly polarized light beams may be written, Equation (3)

\[
\hat{e}_1 = \hat{e}_y = (0, 1, 0) \quad \hat{e}_2 = \hat{e}_z = (0, 0, 1) \quad (3)
\]

If two equal magnitude beams are combined so that one lags \(\pi/2\) or a quarter of a wavelength behind the other, then the electric field vector will trace out a circle giving circularly polarized light. The electric field polarization vector for right circularly polarized light (as defined above) may be written\(^{6–8}\)

\[
\hat{e}_r = \frac{1}{\sqrt{2}} \left\{ (0, 1, -i) \exp \left( \frac{2\pi iX}{\lambda} - iwt \right) \right\} \quad (4)
\]

where \(i\) is the square root of \(-1\). The oscillation of the electric field vector in time is described by the factor \(\exp(-iwt)\) where \(w\) is the angular frequency \((2\pi v)\) and \(t\) is time; the magnitude of the electric field vector remains constant in time, but its direction rotates about \(X\) with frequency \(w\). By taking the real part of Equation (4) we see that for an observer sitting at a fixed point, say \(X = 0\), the electric field vector of right circularly polarized light rotates in time about \(X\) in a clockwise manner. At a fixed time, say \(t = 0\), it forms a right-handed helix in space. In what follows we use the polarization vectors:

\[
\hat{e}_l = \frac{1}{\sqrt{2}} (0, 1, i) \quad \hat{e}_r = \frac{1}{\sqrt{2}} (0, 1, -i) \quad (5)
\]

for, respectively, left and right circularly polarized light, Equation (5).

1.2 Normal Absorption Spectroscopy

Most spectroscopic phenomena arise from the interaction of a molecule with one photon at a time. The molecule either absorbs, emits, or scatters the photon. The simplest form of spectroscopy is absorption, where we measure how much light of a given frequency is absorbed by a collection of molecules. If a molecule absorbs a photon of frequency \(v\), it increases its energy according to Planck’s relationship (Equation 2). Absorbance is defined in terms of the intensity of incident, \(I_0\), and transmitted, \(I\), light, Equation (6):

\[
A = \log_{10} \left( \frac{I_0}{I} \right) \quad (6)
\]

The Beer–Lambert law for the absorption, \(A\), of light by a sample of concentration \(C\) is given by Equation (7):

\[
A = \varepsilon CI \quad (7)
\]

where \(l\) is the length of the sample through which the light passes and \(\varepsilon\) is known as the extinction coefficient; if \(l\) is measured in cm and \(C\) in M (\(=\)mol dm\(^{-3}\)), then \(\varepsilon\) has units of mol\(^{-1}\) dm\(^3\) cm\(^{-1}\). The Beer–Lambert law is valid as long as the spectrometer can measure \(I\) (i.e. the concentration is not so large that essentially all photons are absorbed) and there are no concentration-dependent intermolecular interactions.

In practice, in a collection of molecules, the photons absorbed by different molecules will be of slightly different energies so what we measure is a curve like the absorbance curves of Figure 1, where the signal that is plotted is a measure of the probability that a transition will occur at that energy. Such a plot of the absorbance of light verses \(\lambda\) or \(v\) is known as an absorption spectrum.

1.3 Circular Dichroism Spectroscopy

When a molecule absorbs UV and visible light its electronic distribution is altered. Now consider chiral molecules. Because a chiral molecule has no reflection plane, any rearrangement of its electrons will not have one either, so the electrons move in some kind of helix. As the electric field vectors also trace out helices (Figure 1) in circularly polarized light, the interaction between a chiral molecule and left- and right-handed photons will be different. This is the idea behind the definition of CD given in Equation (1). The CD version of the Beer–Lambert law (Equation 7) is Equation (8):

\[
\Delta A = (\varepsilon_l - \varepsilon_r)CI = (\Delta \varepsilon)CI \quad (8)
\]

Thus, a CD spectrum looks similar to an absorbance spectrum in that it occurs at the same wavelengths (Figure 1), but it can be either positive or negative in sign and if more than one transition lie close together, cancellation of intensity may occur (Figure 3). The challenging task is then to relate the helical motions of the electrons to the arrangement of the atoms and bonds in space.

As noted above, a CD spectrum is only expected for solutions of chiral molecules, though achiral molecules oriented skew to a light beam in an oriented sample, such
as a crystal, will give a signal. The other requirement is that a molecule gives rise to an absorbance signal in the region of interest. If a molecule has no UV/VIS absorbance spectroscopy then no CD signal will be found. Sometimes, as with chiral HPLC (high-performance liquid chromatography) (see below) it is desirable to cause a nonabsorbing molecule to have a CD signal. This may be achieved by derivatizing the analyte molecule with a UV/VIS active chromophore, though care must be taken with the chemistry to ensure inversion of configuration or racemization does not occur.

1.4 Units of Circular Dichroism Spectroscopy

Most CD spectropolarimeters, although they measure differential absorbance, for historical reasons produce a CD spectrum in units of ellipticity, \( \theta \), in millidegrees, versus \( \lambda \), rather than \( \Delta A \) versus \( \lambda \). The conversion between these two is given in Equation (9):

\[
CD = \Delta A/\lambda = \frac{4\pi\theta}{180\ln 10} = \frac{\theta}{32982} \quad (9)
\]

The CD analog of the Beer–Lambert law (Equation 8) then allows conversion to molar absorbance or molar ellipticity. In this context it is important to be clear what concentration is being measured. For example DNA concentrations are often given in terms of bases or phosphates, but may be in terms of base pairs, whereas protein concentrations are commonly in terms of amino acid residues and occasionally whole molecules.

1.5 Optical Activity (Optical Rotation)

Optical rotation (OR) is the difference in refractive indices of left and right circularly polarized light upon passing through the medium, Equation (10):

\[
OR = \frac{n_l - n_r}{\pi d / \lambda} \quad (10)
\]

the units are radians if \( \lambda \) (wavelength) and \( d \) (pathlength) have the same units (usually dm are used). \( (n_l - n_r) \) is called the circular birefringence.

OR is usually measured by determining the rotation of linearly polarized light upon passing through the solution. If the linearly polarized light is rotated clockwise when viewed into the light source the OR is called a positive or right (dextro) OR. OR as a function of \( \lambda \) is called optical rotatory dispersion (ORD). ORD gives an S-shaped curve centered at the CD maximum (the so-called point of anomalous ORD since if a transition has zero band width the ORD would go to plus and minus infinity either side of \( \lambda_{\text{max}} \)). The ORD is also nonzero away from an absorption band, hence \( \sigma_D \) values (the ORD at the sodium D line, 589 nm) may be used to characterize the enantiomeric excess of a solution (see below). The long-wavelength side of the ORD curve shows a positive ORD contribution for a positive CD band, but a negative ORD for a negative CD band. ORD is sometimes referred to as optical activity.

Since ORD and CD may be written respectively in terms of the dispersive and absorptive parts of the optical activity tensors, with all other factors the same, Kramers–Kronig relations may be used to convert one to the other if the complete ORD spectrum or complete CD spectrum is available. The formalism for this process is fairly straightforward; however, in practice the problem is that the “complete” spectrum is not available. It is often possible to perform the conversion on a more limited wavelength range with an element of error. Except for single wavelength measurements to quantify enantiomeric excess, ORD is seldom used now as the more direct
relationship between absorbance spectroscopy and CD facilitates the interpretation of data in structural terms.

1.6 Enantiomeric Purity and Enantiomeric Excess

If a CD signal is observed for a solution, then there is a net excess of a chiral analyte; however, unless $\Delta\varepsilon$ for the compound is known, the enantiomeric purity of the sample cannot be determined. Alternative methods that measure the relative amounts of the two enantiomers directly are chiral HPLC and NMR (nuclear magnetic resonance) with chiral shift reagents. Simply choosing a chiral column or mobile phase additive or chiral shift reagent and then performing an experiment which gives only one peak does not prove that the solution is enantiomerically pure. It must be possible to show that if the mixture is racemic (or any percentage mixture of the two enantiomers) that the experimental method does indeed discriminate between the two species.

Enantiomeric purity is often given in terms of the percentage of one enantiomer present. Alternatively, we use enantiomeric excess. Enantiomeric excess relates more directly to the CD signal because if there is no enantiomeric excess then there is no CD signal; conversely the CD observed follows Equation (8) if the solution is enantiomerically pure. Enantiomeric excess is usually defined as the apparent analyte concentration determined from Equation (8) divided by the total analyte concentration, often converted to a percentage. Equation (11)

$$\text{EE\%} = \frac{100 \times (\text{Concentration of enantiomer 1})}{-(\text{Concentration of enantiomer 2})}$$

(11)

2 STRUCTURE ANALYSIS FROM CIRCULAR DICROISM

2.1 Introduction

The most obvious result to be deduced from the appearance of a CD spectrum is whether or not there is net asymmetry in the sample. It is not much of an overgeneralization to say that the only CD studies that have been interpreted beyond this stage are those where the transition being studied is essentially located in an achiral chromophore (or electronic subunit) of the system. Explicit calculations can, of course, be performed for intrinsically chiral chromophores (such as CHFClBr), however, this does not usually provide any information except that the input geometry for that molecule is correct. By way of contrast, carbonyl compounds containing the achiral chromophore (circled in Figure 4) have been extensively studied using CD spectroscopy and various structure–spectra correlation rules have been proposed and applied. It should be noted that any structure–spectrum correlation rule can only be applied with full confidence once its mechanistic origin is understood.

Given that the chromophores we are interested in are achiral, the electron redistribution that occurs during a transition occurs in a plane. This means that either the magnetic dipole transition moment, $m$, (MDTM) (by which the transition interacts with the magnetic field of the radiation) or the electric dipole transition moment, $\mu$, (EDTM) (by which the transition interacts with the electric field of the radiation) vanishes (or they are perpendicular to one another). The $m = 0$, $\mu \neq 0$ transitions are called electric dipole allowed (EDA), magnetic dipole forbidden (MDF). The $m \neq 0$, $\mu = 0$ transitions are called electric dipole forbidden (EDF), magnetic dipole allowed (MDA). The theoretical significance of this division is due to the way CD intensity is induced into the two different types of transitions. EDA transitions require the induction of a magnetic component, whereas MDA transitions require an induced electric component. The dependence of the different kinds of induced moments on the geometry of the system is very different, so when we wish to extract geometric information from CD we must be aware of which situation is in effect. The CD spectrum induced into EDA transitions is also different if it arises from the coupling of identical chromophores rather than from the coupling of nonidentical chromophores.

Experimentally the difference between EDA/MDF and EDF/MDA transitions is that the latter have low absorbance intensity (what they have is usually gained from vibronic coupling rather than from the MDTM) so the ratio of their CD signal to their absorbance is larger than that for EDA/MDF transitions. The dissymmetry factor, $g$, Equation (12)

$$g = \frac{4R}{cD}$$

(12)

where $R$ is the rotational CD strength (Equation 30), $c$ is the speed of light, and $D$ is the dipole strength (square of the EDTM) of the transition summarizes this. The
main historical consequence of this is that most of the early CD experiments were performed on EDF/MDA transitions such as the \( n \rightarrow \pi^* \) carbonyl transitions and the T\(_{1g} \) tris-chelate transitions.

### 2.2 Qualitative Description of Circular Dichroism and Its Correlation with Structure for Some Systems

#### 2.2.1 Carbonyl Circular Dichroism

Carbonyl chromophores, i.e. carbonyl functional groups that are not conjugated with any other double bond of the molecule, occur in many organic molecules of both natural and synthetic origin including steroids. That a simple reliable empirical rule relating carbonyl molecular geometry to observed CD spectrum was determined and to some extent rationalized in the 1960s was therefore extremely convenient. The lowest lying transition of a carbonyl is the \( n \rightarrow \pi^* \) transition which involves rotation of electron density from the nonbonding oxygen lone pair into the \( \pi^* \) orbital of the C=O bond (Figures 4 and 5). The transition, which occurs somewhere between 350 nm and 240 nm, is weak with an extinction coefficient typically of 20–50 mol\(^{-1}\) dm\(^3\) cm\(^{-1}\). When it is conjugated with a double bond as in progesterone (Figure 4) the absorbance intensity is increased and any rules to interpret the CD spectra must be applied with care. The octant rule of Moffitt et al.\(^{(11)}\) is the unifying feature for much of the carbonyl CD work. In its original form, the rule stated that the CD of the \( n \rightarrow \pi^* \) transition depends on the positions of other parts of the molecule relative to the carbonyl group according to Equation (13)

\[
\Delta \varepsilon = \frac{xyz}{r^n}
\]

where \((x,y,z)\) is the unit vector along the lines of the position vector in the right-handed coordinate system of Figure 5 and \(r\) is the distance from the centre of the carbonyl bond to the chromophore. Höhn and Weigang\(^{(12)}\) used perturbation theory to give a theoretical justification of the octant rule and found that \(n = 4\), and that the relative importance of different parts of the molecule scaled with their polarizability. This was the first use of what has come to be called the independent systems/perturbation (ISP) approach.\(^{(13–15)}\)

To apply the octant rule to hydrocarbon systems, one simply determines the cartesian coordinates of each carbon atom (assuming the hydrogens make little contribution), evaluates Equation (13) with \(n = 4\) and performs a sum over all carbons in the molecule (or in practice over the net perturbers since atoms located symmetrically about a plane of the octant system will give equal magnitude and opposite sign contributions). An example is given in Figure 6. A simple Gaussian type curve with sign and relative magnitude determined by this sum should then correlate with the observed CD. For nonhydrocarbon systems, the sum must be weighted by the polarizabilities of the atoms or chromophores (see below) of the molecule.\(^{(16)}\)

Although the octant rule has proved to be highly successful, there are sufficiently numerous exceptions to provide a warning against the blind use of empirical rules. Empirical modifications (see Rodger and Rodger and references therein),\(^{(15)}\) while helpful for a given series of compounds, do not provide a global approach. Consideration of all terms in the ISP expansion (see below) is really required. The conclusion from this

![Figure 5](image)

**Figure 5** (a) Schematic illustration of the carbonyl \( n \rightarrow \pi^* \) transition illustrating the \((x,y,z)\) coordinate system used for the octant rule. (b) Octant rule CD signs. Invert the signs illustrated for the \(x < 0\) region of space.

![Figure 6](image)

**Figure 6** Projection onto the \(x-y\) octant plane of levonorgestrel butanoate viewed along the carbonyl bond. All atoms (except the carbonyl oxygen) have coordinates with \(z < 0\). Octant signs are as indicated. The size of the carbon atoms indicates their proximity to the carbonyl group (large ones are close). The dominant octant rule net perturber lies in the \(x < 0, y > 0, z < 0\) octant (although more distant atoms lie in the \(x < 0, y < 0, z < 0\) octant) Oxygen atoms are shaded. Thus, a positive \( n \rightarrow \pi^* \) CD signal is expected from this molecule. In fact \(\Delta \varepsilon_{322\,\text{nm}} = 1.5\,\text{mol}^{-1}\cdot\text{dm}^3\cdot\text{cm}^{-1}\).\(^{(15)}\)
analysis is that the octant rule is not valid for polar and charged groups. It also requires the net perturbing part of the system not to lie on or near one of the octant planes. Further, no solvent cavities must be created by substituents on the molecules and planar zig-zags of bonds with the carbonyl bond must be absent for the CD magnitude to be given by the octant rule.

2.2.2 Transition Metal Complexes

The spectroscopy of transition metal complexes can be subdivided into three categories: in-ligand transitions, which resemble those of the isolated ligands; charge-transfer transitions between the ligand and the metal; and d–d transitions of the chromophore defined by the central metal ion and its directly ligating atoms.

The in-ligand transitions need only be considered for aromatic ligands since they are the only ones for which the CD can be easily measured. This effectively restricts consideration to tris-chelate (and also cis bis-chelate) complexes with planar aromatic ligands. The ligands in such molecules are usually of $C_{2v}$ symmetry (Figure 7). The in-ligand CD for these systems can usually be accurately predicted by the Kirkwood–Kuhn coupled oscillator mechanism (see below). As the complexes are based on an octahedral template but themselves have $D_3$ symmetry, the transitions all occur as couplets of $A_2$ (z, the three-fold axis, Figure 7) polarized and $E_u$ ($x, y$) polarized transitions. The coupling of long axis ligand transition moments gives a bisignate CD signal the lower energy component being the out-of-phase $E_u$ component that has a negative sign for the $1\overline{1}$ enantiomer and conversely for the $3\overline{3}$ enantiomer (see below for the theoretical basis for this conclusion). The $A_2$ component (in the absence of coupling with other transitions) is equal in magnitude and opposite in sign from the $E_u$ component as illustrated in Figure 3.

Charge transfer CD has also been measured mainly for tris-chelate complexes with planar aromatic ligands. For such molecules the charge transfer bands often obscure the d–d transitions. The lowest energy EDA charge transfer transitions for tris-chelate complexes gives a bisignate signal ($E_u/A_2$) with the $E_u$ component having the opposite sign from the lowest energy long-axis in-ligand $E_u$ CD (see above). The sign difference can be used to assign the polarization of the charge transfer bands whose energy ordering varies from molecule to molecule, in contrast to the situation for the in-ligand transitions.

Interpreting the CD for the MDA d–d transitions (CD for MDF/EDF is usually very small) is complicated by the fact that the dominant mechanism is determined by the symmetry of the d–d chromophore. One reliable empirical rule has been established over the years for tris-chelate complexes where transitions of $E$ and $A_2$ polarization occur as close lying couplets: the $E$ band CD signal is larger than the $A_2$ band signal. The underlying reason for this is that if we take the d–d chromophore to have $D_3d$ symmetry (Figure 8) then the $E_g$ band gains its CD intensity from a $r^4$ quadrupolar mechanism (see below), whereas the $A_2$ band depends on an $r^6$ hexadecapolar mechanism as discussed below. In reality the d–d chromophore of tris-chelate complexes is not achiral but twisted. However, for solution phase work the approximation is satisfactory as the close energy of the $A_2$ and $E$ components of any band means that any intrinsic CD cancels as it would for the octahedral parent geometry. It is only for crystal CD that the problem is noted.

2.2.3 Macromolecules

The CD of macromolecules differs from that of small molecules in that the spectroscopy of the component

---

**Figure 7** $[\text{Ru}(1,10\text{-phenanthroline})_3]^{2+}$, a tris-chelate transition metal complex of $D_3$ symmetry with $C_{2v}$ symmetry planar aromatic ligands. The three-fold ($z$) axis is out of the plane of the page in the right-hand side of the figure.

**Figure 8** $D_{3d}$ d–d chromophore of $[\text{Co}(\text{ethylenediamine})_3]^{3+}$, ethylenediamine = NH$_2$CH$_2$CH$_2$NH$_2$. 
parts, such as the amino acids, at least in principle, is usually understood and the form of the CD spectra result largely from the arrangement of the units in space. The CD of macromolecules is most commonly used in one of two ways: (i) to probe changes in the conformation of the macromolecule itself, and (ii) to probe its interaction with small molecules bound to it.

2.2.4 Proteins

At present the main use of CD in the study of proteins is as an empirical gauge of protein structure and conformation. Proteins are long chains of amino acids, their primary structure being as illustrated in Figure 9. If the side chain ($R_i$ in Figure 9) is not H, then the $i$th tetrahedral carbon is a chiral center and we should expect an induced CD signal in transitions of the neighboring amide groups and side chains. If, however, there is free rotation about the bonds of the main chain, the observed amide $n \rightarrow \pi^*$ (occurring at $\sim 220$ nm), $\pi \rightarrow \pi^*$ (occurring at 207–190 nm), and $n \rightarrow \sigma^*$ (occurring as a shoulder at 175 nm) CD signals will be small since they will be an average of different geometry factors (see carbonyl CD above and coupled oscillator CD below). Thus a truly random or denatured protein will have only a small CD signal at energies accessible to most CD machines. The most stable conformation of a protein under physiological conditions, however, is not random but composed of well-defined structural units that give macrochiral units with significant CD intensities.

The basis of CD structural analysis of proteins is that the CD spectrum from 250 nm downwards is due largely to transitions of the main backbone chain, so it is independent of the nature of the side chains (this is not always true if there are a large number of well-ordered aromatic side chains or prosthetic groups such as a heme present). In any well-defined structural motif (such as the $\alpha$-helix where the $n$th peptide unit forms hydrogen bonds between its C–O and the N–H of the $(n + 4)$th peptide and between its N–H and the $(n – 4)$th C–O; there is a 1.5 Å translation and 100° turn between two consecutive peptide units, giving 3.6 amino acid residues per turn), the chromophores giving rise to the CD are in well-defined positions relative to one another so have a well-defined CD spectrum. The net CD is then the sum of that due to the independent structural units. A wide range of fitting programs for protein CD data are available. Some work in terms of the spectra of a set of identified structural

![Figure 9](image_url)  
**Figure 9** Protein primary structure. $R_i$ denotes the side chain of the $i$th amino acid.
motifs, others use a basis set of real protein spectra where the percentage of different structural units is known. The approach of Manalavan and Johnson, where a large basis set of such proteins is used and a subset of these randomly chosen until a good fit is obtained probably gives the best estimate of the full range of structural motifs present in proteins. Almost all approaches will give a good \( \alpha \)-helix content estimate as its profile is the most distinct and also largest in magnitude as illustrated in Figure 10.

2.2.5 DNA

CD experiments performed on DNAs generally fall into one of two categories: those used to probe the DNA and those used to probe a drug (or other molecule) bound to the DNA. DNA can be viewed as a more-or-less vertical spiral staircase where the steps are made up of pairs of planar aromatic molecules, called base pairs, and the sides are chains of alternating phosphate groups and ribose sugars. The source of the chiral structure in DNA is the sugar backbone which imposes the twisted structure onto the whole molecule. Usually the twist is right-handed, though it appears that left-handed Z-DNA is intrinsically not much less stable than the right-handed forms. The CD of a DNA molecule in the 180–300 nm region is due to the skewed orientation of transitions in the bases. Thus, if the DNA is untwisted there will be less CD and if it is twisted the other way the relative geometries of the coupling transition moments (see below) will change and the CD signal may even invert (as it does for Z-DNA relative to much of the B-DNA spectrum, Figure 11).

2.2.6 Induced Circular Dichroism of a Molecule Bound to DNA

If an achiral molecule is bound to DNA, its transitions gain an induced circular dichroism (ICD) due to perturbation by the chiral DNA. The sign and magnitude of this ICD is crucially dependent on the binding geometry, so in principle should yield information about that binding geometry. At its crudest level the appearance of the CD signal indicates that the drug molecule is bound. If the binding is in a single binding mode or a constant proportion of mixed modes then the ICD signal will be proportional to the concentration of bound drug and a titration series of data can be used to determine the binding constant of the drug to DNA. An example is given in Table 1 and Figure 12.

2.3 Interaction of Radiation with Matter and the Rosenfeld Equation for Circular Dichroism

In classical mechanics, the energy of the interaction, \( H_{\text{int}} \), between a molecule and the electric, \( \mathbf{E} \), and magnetic, \( \mathbf{B} \), fields of electromagnetic radiation is given by Equation (14):  

\[
H_{\text{int}} = -\mu \mathbf{E} - m \mathbf{B} + \text{higher order multipole terms}
\]

where \( \mu \) is the electric dipole moment of the molecule and \( m \) is its magnetic dipole moment. \( \mu \) and \( m \) are determined by summing over the electron distribution of the molecule, Equation (15):
The ICD signal for the \( b \) spectrum. The intercept equals the concentration (i.e. the DNA concentration divided by \( D \)) determined for calf thymus DNA with \( pH = 7 \).

**Table 1** Induced CD signals at 215 nm (DNA signal subtracted out) determined for calf thymus DNA with additions of [Co(NH₃)₆]³⁺.

**Figure 12** (a) Induced spectroscopy method plot⁸,²⁸ where \( x = \left( \frac{L_{\text{tot}}}{\rho} \right) - \frac{L_{\text{tot}}}{\rho^2} \) and \( y = \frac{L_{\text{tot}}}{\rho} = \frac{1}{\rho} \) for \( \rho \) the ICD signal for the \( i \)th spectrum, and \( L_{\text{tot}} \) the ligand concentration for that spectrum. The intercept equals \( \alpha \), where \( \alpha \) relates the bound ligand concentration to the ICD \( \rho \); \( L_b = \alpha \rho \), and \( n \) is the number of DNA bases per bound ligand. The slope is \( S_{\text{tot}}/\alpha \) where \( S_{\text{tot}} \) is the total binding site concentration (i.e. the DNA concentration divided by \( n \)). From the graph: \( \alpha = 9.3 \pm 1 \mu \text{m deg}^{-1} \); \( n = 16 \pm 2 \). (b) Scatchard plot⁸,²⁸ using value of \( \alpha \) determined from (a). \( r \) is binding ratio (concentration of ligand bound divided by DNA base concentration), \( L_i \) is the concentration of free ligand. The slope is \( -K \), for \( K \) the equilibrium binding constant. The binding constant is therefore approximately 100 000 M⁻¹.

where \( e \) is the (negative) unit charge on an electron, \( r_i \) denotes the position vector of the \( i \)th electron, \( p_i \) is the momentum vector for the \( i \)th electron, and \( m_e \) is the mass of an electron.

When we are interested in spectroscopic phenomena such as absorbance, CD, and LD (see below), we have to move beyond classical mechanics to quantum mechanics since the transitions we study involve discrete amounts of energy, i.e. the energy is quantized. Thus, instead of an expression for the classical energy of the interaction between the radiation and the molecule, we need the interaction Hamiltonian operator.(³–⁵,⁷) This follows from Equation (14) by converting \( \mu \) and \( m \) to operators and the interaction energy to the Hamiltonian operator. Curved ‘hats’ are used in what follows to denote operators, Equation (16):

\[
\hat{H}_{\text{int}} = -\hat{\mu}E - \hat{m}B + \text{higher order terms} \quad (16)
\]

When we compare the relative strengths of different transitions experimentally we measure the intensity of the transition which is the area under the absorption band. The related theoretical quantity is the probability per unit time, \( P \), that a transition will occur from the initial state, \( |i\rangle \), (which is usually the ground state) to the final state, \( |f\rangle \):³–⁵,⁷

\[
P(|i\rangle \rightarrow |f\rangle) = k'(|i\rangle |\hat{H}_{\text{int}}|i\rangle)^2 = k'(|f\rangle |\hat{H}_{\text{int}}|f\rangle |\hat{H}_{\text{int}}|i\rangle = k'(|i\rangle |\hat{H}_{\text{int}}|f\rangle |\hat{H}_{\text{int}}|i\rangle \quad (17)
\]

where the integral is over molecular position coordinates, and \( k' \) is a constant. Equation (17) is a form of the Fermi Golden Rule.³–⁵,⁷ It is written in terms of bra–ket notation where the ‘bra’ \( |0\rangle \) state is the complex conjugate of the ‘ket’ \( |0\rangle \). When a bra and a ket are coupled together either directly or either side of an operator, such as \( \mu \) in Equation (18) below, then we imply that an integral over all space is being performed. Round brackets \( |\rangle \) in what follows denote unperturbed states of chromophores A and C (see below), and pointed ones \( \rangle \) denote the states of the whole system. Upon substituting the expression for \( \hat{H}_{\text{int}} \) into Equation (17) we have Equation (18)

\[
P(|i\rangle \rightarrow |f\rangle) = k\langle i|\hat{\mu}|f\rangle \hat{e}^\ast + \langle i|m|f\rangle \hat{b}^\ast \times \langle f|m|i\rangle \hat{e} + \langle f|m|i\rangle \hat{b} \quad (18)
\]

where \( \hat{e} \) is the unit vector along \( \mathbf{E} \), \( \hat{b} \) is the unit vector along \( \mathbf{B} \), the asterisk denotes the complex conjugate, \( |i\rangle^\ast = |i\rangle \), and the magnitudes of the electric and magnetic fields are absorbed into the constant \( k \). \( |f|m|i\rangle \) is the EDTM from state \( i \) to state \( f \), and \( |f|m|i\rangle \) the corresponding MDTM.
It follows that (8) Equation (19)

\[ P(i) \rightarrow |f\rangle = k[\mu^f e^* \mu^i + m^f \hat{b}^* m^i \hat{b}]_{(1)} + k[\mu^f e^* m^i \hat{b} + \mu^i e^* m^f \hat{b}]_{(II)} \]  

(19)

where \( \mu^f = \mu^{i\rightarrow f} \) and \( |f\rangle |m\rangle \) and so on (note inversion of order of states in the notation).

2.3.1 Interaction of a Molecule with Linearly Polarized Light: Absorbance and Linear Dichroism

If no external magnetic field is present (except that due to the radiation) we can choose \( |i\rangle \) and \( |f\rangle \) to be real wavefunctions; thus \( \mu^f = \mu^i \) but \( m^f = -m^i \) since \( m \) is imaginary. The polarization vectors for \( \mathbf{E} \), and hence \( \mathbf{B} \), are also real for linearly polarized light. It follows that the two parts of term (II) in Equation (19) are equal in magnitude but opposite in sign, so term II is zero. As magnetic terms are invariably small compared with electric ones, we can ignore the second term within term (I) and therefore write the probability of the transition occurring from \( |i\rangle \) to \( |f\rangle \) with light polarized parallel to the electric field (the absorbance, \( A_e \), of the transition) to be:

\[ A_e(|i\rangle \rightarrow |f\rangle) = k|\mu^f e^i|^2 \]  

(20)

For the usual situation where the system is a collection of randomly oriented molecules, the interaction averages to \( \frac{1}{3} \) Equation (20) and becomes Equation (21): \( \frac{1}{3} \) Equation (20)

\[ A_{iso} = A = \frac{k}{3} |\mu^f e^i|^2 \]  

(21)

where \( A_{iso} \) is the isotropic absorbance. LD, which forms the subject matter of the next section, is the difference in absorption of two in-phase linearly polarized light beams propagating in the same direction with perpendicular polarizations. Take the \(|i\rangle \) direction to be \((0,0,1)\) and the perpendicular direction to be \((0,1,0)\). Then Equation (22) follows from Equation (20)

\[ \text{LD}_{\text{molecule}} = (A_{||} - A_{\perp})_{\text{molecule}} = k[|\mu^f e^i|^2 - |\mu^f m^i|^2] \]  

(22)

where \( \mu^f_{||} \) is the \( Y \) component of \( |i\rangle \) to \( |f\rangle \) transition dipole moment, and so on. For a collection of \( N \) molecules we sum over the LD for each molecule, Equation (23)

\[ \text{LD}_{\text{total}} = \sum_{\text{molecules}} (A_{||} - A_{\perp})_{\text{molecule}} = Nk(|\mu^f_{||}|^2 - |\mu^f_{||}|^2) \]  

(23)

where \( \langle \rangle \) denotes average. The net LD thus depends on the method and extent of sample orientation since \( X, Y, Z \) is a laboratory-fixed axis system about which the molecule knows nothing unless we tell it. In the absence of any molecular orientation the LD in Equation (23) vanishes because all molecular axes are equally likely to coincide with \( Z \) so, Equation (24)

\[ \langle |\mu^f_{||}|^2 \rangle = \langle |\mu^f_{||}|^2 \rangle = \frac{1}{2} |\mu^f|^2 \]  

(24)

2.3.2 Interaction of a Molecule with Circularly Polarized Light: Circular Dichroism

When the radiation is circularly polarized, CD becomes possible. As long as there is no magnetic field (apart from that of the radiation) present, we can again choose to use real wavefunctions so \( \mu^f = \mu^i \) and \( m^f = -m^i \). To evaluate Equation (1) we substitute first the expression for left circularly polarized light into Equation (19) then subtract from it the result of substituting the expression for right circularly polarized light. We also make use of the equality \( \hat{e}_r = \hat{e}_l \), and note that, \( \frac{1}{6} \) (6-8) Equations (25) and (26)

\[ \mathbf{b} = k\hat{e} \]  

(25)

so

\[ \mathbf{b}_1 = \frac{1}{\sqrt{2}} (1, 0, 0) (0, 1, i) = \frac{1}{\sqrt{2}} (0, -i, 1) = \hat{b}_r \]  

(26)

Thus (6)

\[ \text{CD} = A_1 - A_r \]

\[ = k [\mu^f \hat{e}_r \mu^i \hat{e}_l + m^f \hat{b}_r m^i \hat{b}_l] - k [\mu^f \hat{e}_l m^i \hat{b}_r + \mu^i \hat{e}_r m^f \hat{b}_l] \]  

(27)

Because \( \mu^f \hat{e}_r \mu^i \hat{e}_l = \mu^f \hat{e}_l \mu^i \hat{e}_r \) and so on (the wavefunctions are real), the term (I) vanishes. Upon rearranging term (II) so that the EDTMs are all from \((f)\) to \((i)\) and the magnetic moments are the reverse, Equation (27) becomes Equation (28)

\[ \text{CD} = A_1 - A_r = 2k[\mu^f \hat{e}_l m^i \hat{b}_r - \mu^i \hat{e}_r m^f \hat{b}_l] \]  

(28)

Substitution of explicit forms for the electric and magnetic field (Equations 5 and 25) polarizations for the circularly polarized radiation, gives Equation (29)

\[ \text{CD} = -2i \text{Im}[\mu^f m^i \mu^f m^i] = 2\text{Im}[\mu^f m^i \mu^f m^i] \]  

(29)

where ‘Im’ denotes ‘the imaginary part of’.

CD experiments are usually performed on collections of randomly oriented molecules. In that case the laboratory (radiation) defined axis system does not relate in any fixed way to a molecular axis system, so what
is measured is a rotational average of Equation (29) in Equation (30a):

$$\text{CD} = \frac{2}{3} k \langle \hat{m} | \hat{f} \rangle \langle \hat{f} | \hat{m} \rangle = \frac{2}{3} k \text{Im} [\mu^\alpha \mu^\beta]$$  \hspace{1cm} (30a)

The CD for the transition from state $|i\rangle$ to state $|f\rangle$ is thus given by the Rosenfeld equation (Equation 30b):\(^{(20)}\)

$$\text{CD} = \text{Im}[\mu^\alpha \mu^\beta]$$  \hspace{1cm} (30b)

Recall that $\mu^\beta$ is the EDMT from state $|f\rangle$ to state $|i\rangle$.

If we limit our consideration to achiral molecules but impose an external magnetic field, then term (II) of Equation (27) vanishes, but term (I) does not (the states are complex rather than real). Further, we ignore the terms that involve squares of MDTMs as they will be much smaller than any EDTM terms. The magnetic circular dichroism (MCD) may then be written as Equation (31)

$$\text{MCD} = k [c_2 \mu^\alpha \mu^\beta - c_1 \mu^\beta \mu^\alpha]$$

$$\text{MCD} = 2i k (\mu^\alpha \mu^\beta - \mu^\beta \mu^\alpha)$$  \hspace{1cm} (31)

We shall not deal further with MCD in this article. See Rodger and Nordén\(^{(8,31)}\) for more details.

2.4 Circular Dichroism of Magnetic Dipole Allowed Transitions: Why the Octant Rule Works for Carbons

In this section and the next we shall be working within the chromophoric or independent systems/perturbation (ISP) approach to CD theory,\(^{(8,12,13,15)}\) and will limit our consideration to transitions in achiral chromophores, $A$, that acquire CD intensity by coupling to transitions in other chromophores $C$. $C$ need not itself be chiral but it must be positioned so that $[A + C]$ forms a chiral system. A chromophore is strictly a part of a system whose wavefunctions have no overlap with the rest of the system; electronic wavefunctions in a chromophore therefore have no electron exchange with the rest of the system. In practice, a chromophore is usually identified for a given electronic transition if that transition seems to be more or less dependent on only the identity of a subset of the molecule (such as the carbonyl functional group).

We also need to be able to write an equation for the interaction between $A$ and $C$. Since there is no electron exchange between $A$ and $C$ (by definition), their interaction, $V$, is purely coulombic, Equation (32)

$$V = \sum_{a,c} \frac{q_a q_c}{|R_{AC} + r_c - r_a|}$$  \hspace{1cm} (32)

where $q_a$ is the charge of a particle in $A$ located at the end of the vector, $r_a$, that begins at the $A$ origin, similarly $q_c$ and $r_c$, and $R_{AC} = R_C - R_A$ is the vector from the origin of chromophore $A$ to the origin of chromophore $C$ (Figure 13).

The electric dipole moment operator, $\vec{\mu}$, where $\sim$ is used here to indicate an operator for the whole system, may be written in terms of $A$ and $C$ operators as, Equation (33)

$$\vec{\mu} = e \sum_a (\hat{R}_A + \hat{r}_a) + \sum_c (\hat{R}_C + \hat{r}_c)$$  \hspace{1cm} (33)

where $\hat{R}_A = R_A$ is the position operator for the $A$ origin in the global coordinate system, and $\hat{r}_a = r_a$ is the position operator within $A$ for particle $a$ (Figure 13). We shall be considering only transition moments, so since $\hat{R}_A$ is constant it follows that\(^{(8)}\)

$$\vec{\mu} = e \left( \sum_a (\hat{r}_a) + \sum_c (\hat{r}_c) \right) = \vec{\mu}_A + \vec{\mu}_C$$  \hspace{1cm} (34)

where $\vec{\mu}_A$ is the electric dipole moment operator for $A$ and operates only on wavefunctions of $A$.

Similarly it follows from Equation (15) that the magnetic dipole moment operator for the whole system is,\(^{(8)}\) Equation (35)

$$\hat{m} = \hat{m}_A + \hat{m}_C$$

$$\hat{m} = \frac{e}{2m_e} \sum_a (\hat{R}_A + \hat{r}_a) \hat{p}_a + \sum_c (\hat{R}_C + \hat{r}_c) \hat{p}_c$$

$$\hat{m} = \frac{e}{2m_e} \hat{R}_A \sum_a \hat{p}_a + \hat{m}_A + \frac{e}{2m_e} \hat{R}_C \sum_c \hat{p}_c + \hat{m}_C$$

$$\hat{m} = \frac{e}{2m_e} \hat{R}_A \hat{p}_A + \hat{m}_A + \frac{e}{2m_e} \hat{R}_C \hat{p}_C + \hat{m}_C$$  \hspace{1cm} (35)

where $\hat{m}_A$ is the total magnetic moment for chromophore $A$, $\hat{p}_A$ is the linear momentum operator for chromophore $A$, $\hat{m}_A$ is the intrinsic magnetic dipole moment operator within $A$, and so on. Thus the total magnetic moment for $A$ includes both the intrinsic magnetic moment operator within the chromophore and any magnetic moment due to the linear motion of its charges about the system origin.
To evaluate the Rosenfeld equation (Equation 30b) for two interacting chromophores we need to know \( \mu^{01} \) and \( m^{01} \) for the whole system, i.e. for the \( |0\rangle \rightarrow |1\rangle \) transition, which is the \( |0\rangle \rightarrow |1\rangle \) transition on A in the presence of any perturbation due to C. We write the wavefunctions for the A/C system when their interaction is switched off as the product wavefunctions \( |a\rangle|c\rangle = |ac\rangle \) where \( |a\rangle \) is a wavefunction of A and \( |c\rangle \) a wavefunction of C. The A function is always written first even in the ket form, thus, Equation (36)

\[
|\langle a|c\rangle|^* = |\langle ac\rangle|^* = \langle a|c\rangle = \langle ac\rangle
\]

A operators only operate on A wavefunctions, similarly C operators only operate on C wavefunctions. For example, Equation (37)

\[
(a'|c|\mu_A|ac) = (a'|\mu_A|a)(c'|c) = \mu_A^{ac}\delta_{a'c'}
\]

where \( \delta_{a'c'} = 0 \) unless \( c' = c \).

We are considering the situation when the \( |0\rangle \rightarrow |1\rangle \) transition of A is MDA and EDF so \( m_A^{00} \neq 0 \) but \( \mu_A^{00} = 0 \). An EDF transition of an achiral chromophore, A, must ‘borrow’ some electric character in order to have a CD signal. If we also assume that transition moments give significantly stronger effects than permanent moments, then the ‘dynamic coupling’ model for the CD of MDA transitions follows. Historically much more effort has been put into what is known as the ‘static coupling’ or ‘one electron’ mechanism (since one electron on A is assumed to be the only one to move) where the molecular framework provides a static perturbation via permanent moments. This mechanism certainly contributes to the net observed CD, however, its contribution is almost always smaller than that due to the dynamic coupling mechanism. More details about the static coupling model may be found in references in Schellman.

To determine the wavefunctions of the interacting A/C system we first consider an A/C system where A and C do not interact. The Hamiltonian, \( \hat{H} \), of the noninteracting system is the sum, Equation (38)

\[
\hat{H} = \hat{H}_A + \hat{H}_C
\]

where \( \hat{H}_A \) is the Hamiltonian of isolated A, and similarly \( \hat{H}_C \). This Hamiltonian is separable and the total energy of a state \( |ac\rangle \) is the energy of \( |a\rangle \) in A plus that of \( |c\rangle \) in C. So, for example, \( |01\rangle \) means A is in its ground state and C is in state \( |1\rangle \). The energy of the \( |01\rangle \) state of the combined system is therefore \( 0 + \varepsilon = \varepsilon \) (taking the zero point of energy to be when both A and C are in their ground states).

When the electrostatic interaction, \( V \) (Equation 32), is ‘switched’ on between A and C then the Hamiltonian of the interacting system is, Equation (39)

\[
\hat{H} = \hat{H}_A + \hat{H}_C + V
\]

The wavefunctions for the combined system could be determined using the Equation (32) expression for \( V \) and the variation principle. We shall use perturbation theory to give expressions for the wavefunctions and later assume that A and C are far enough apart to expand \( V \) as a double Taylor series expansion to give terms dependent on monopoles, dipoles, quadrupoles and so on of A and C. This approach has the disadvantage of giving different final equations for degenerate and nondegenerate systems (and ignores near degenerate systems); however, it has the advantage of enabling us to write equations that can be used to relate system geometry to CD signal.

The perturbed wavefunctions \( |i\rangle = |00\rangle \) and \( |f\rangle = |10\rangle \) for the MDTM case where the perturbation comes from EDTMs are determined from nondegenerate perturbation theory to first order in \( V \) Equations (40) and (41),

\[
|00\rangle = |00\rangle - \frac{(1c|V|00)}{\varepsilon_c + \varepsilon_a}|1c\rangle
\]

\[
|10\rangle = |10\rangle - \frac{(0c|V|10)}{\varepsilon_c - \varepsilon_a}|0c\rangle
\]

from which it follows that, Equation (42)

\[
\mu^{01} = \langle 00|\mu_{10}|10\rangle = \langle 00|\mu_A + \mu_C|10\rangle
\]

\[
= \langle 00|\mu_A|10\rangle - \frac{(00|V|1e)}{\varepsilon_c + \varepsilon_a}(1c|\mu_C|10)
\]

\[
- \frac{(0c|V|10)}{\varepsilon_c - \varepsilon_a}(00|\mu_{0c}|0c)
\]

\[
= \frac{(00|V|1c)}{\varepsilon_c + \varepsilon_a} - \frac{(0c|V|10)}{\varepsilon_c - \varepsilon_a} - \mu_{0c} = -\frac{2\varepsilon_c V^{1c}}{\varepsilon_c^2 - \varepsilon_a^2} - \mu_{0c}
\]

since the A and C wavefunction are real. Similarly, Equation (43)

\[
m^{01} = |10|\bar{m}|00\rangle = (10|m_A + m_C|00) = (10|m_A|00) - \frac{(1c|V|00)}{\varepsilon_a + \varepsilon_c}(10|m_C|1c)
\]

\[
- \frac{(10|V|0c)}{\varepsilon_a - \varepsilon_c}(00|m_{0c}|00)
\]

\[
= \frac{(1c|V|00)}{\varepsilon_a + \varepsilon_c} m_C^{0e} - \frac{(10|V|0c)}{\varepsilon_a - \varepsilon_c} m_{0e}
\]

\[
= \frac{2\varepsilon_a V^{1c}}{\varepsilon_c^2 - \varepsilon_a^2} m_C^{0e}
\]

Substitution into the Rosenfeld equation (Equation 30b) gives the so-called dynamic coupling CD expressions to first order in \( V \).
\[ R = \text{Im} \left\{ -2\varepsilon_c V^{lc} \frac{\mu_m m_{A}^{\text{e}}}{\varepsilon_c^2 - \varepsilon_s^2} \right\} \]  

(44)  

The above equations are for systems composed of A plus one C. If there are two or more Cs then a sum over Cs is introduced.

In order to apply Equation (44) we need to have explicit forms for \( V^{lc} \) in terms of electric transition moments of A and C. It is now convenient to use a general form for the terms in the expansion of \( V \) using \( i, j, k = (x, y, z) \) and the Kronecker delta, \( \delta_{ij,} \) which is zero unless \( i = j \). The dipole–dipole term in the expansion of \( V \) is \(^{(20)}\) given in Equation (45)

\[ V^{lc}(\mu_A - \mu_C) = V^{10.0c} = (0c|V|10) \]

\[ = \frac{\mu_A^{10} \mu_C^{0c} - 3\hat{\mu}_{AC}^{10} \mu_C^{0c} \hat{R}_{AC}}{R_{AC}^3} \]

\[ = \frac{1}{R_{AC}^3} (\mu_A^{10}(\mu_C^{0c})_{ij} - 3(\hat{\mu}_{AC}^{10}(\hat{R}_{AC})_{ij})) \]  

(45)

where a sum over all repeated indices is implied. When substituted into Equation (44) the dipole–dipole term of \( V \) leads to a CD expression containing a \( (\mu_A^{10})(m_C^{01})_k \) term. This moment product vanishes except for chromophores of \( C_2 \) symmetry (i.e. those with only one reflection plane and no rotation axes) and \( x \)- and \( y \)-polarized transitions of \( C_{2v} \) chromophores. An MDA transition in such a chromophore is also EDA so the CD will probably be dominated by the coupled-oscillator CD of the EDTM which is dependent on \( (\hat{R}_{AC})^{-2} \) (see below).

For magnetically \( z \)-polarized transitions in A chromophores of \( C_{2v} \) symmetry such as the \( n \rightarrow \pi^* \) transition of carbonyls (see above) the quadrupole–dipole term of \( V \) is the first nonvanishing one. Equation (46):\(^{(14)}\)

\[ V^{lc}(Q_A - \mu_C) = -\frac{3}{2R_{AC}^3} [(Q_A^{10})_{ij}(\mu_C^{0c})_k] \]

\[ \times \delta_{ij} (\hat{R}_{AC})_k + \delta_{ik} (\hat{R}_{AC})_j + \delta_{jk} (\hat{R}_{AC})_i \]

\[ - 5 (\hat{R}_{AC})_i (\hat{R}_{AC})_j (\hat{R}_{AC})_k \]  

(46)

where \( Q_A \) is the electric quadrupole moment operator of A. It is a second rank tensor whose components are, Equation (47)

\[ (Q_A)_{ij} = \varepsilon \sum_a \langle r | r_a \rangle \]  

(cf. Equation 15 for notation). The quadrupole–dipole CD term is thus given by Equation (48)

\[ R = -\frac{3}{R_{AC}^4} \text{Im} \left\{ (Q_A^{10})_{ij}(m_C^{01})_k \right\} \frac{\varepsilon_c(\mu_C^{0c})_i(\mu_C^{0c})_j}{(\varepsilon_c^2 - \varepsilon_s^2)} \]

\[ \times \delta_{ij} (\hat{R}_{AC})_k + \delta_{ik} (\hat{R}_{AC})_j + \delta_{jk} (\hat{R}_{AC})_i \]

\[ - 5 (\hat{R}_{AC})_i (\hat{R}_{AC})_j (\hat{R}_{AC})_k \]  

(48)

Unless \( i, j \) equals \( x, y \) or \( y, x \) the A-moment product (first square brackets in Equation 48) vanishes. Thus the CD strength for MDA \( z \)-polarized transitions of \( C_{2v} \) chromophores such as the \( n \rightarrow \pi^* \) transition of carbonyls (Figure 4) is, Equation (49):\(^{(15)}\)

\[ R(C_{2v}, z) = -\frac{6}{R_{AC}^4} \text{Im} \left\{ (Q_A^{10})_{ij}(m_C^{01})_k \right\} \frac{\varepsilon_c(\mu_C^{0c})_i}{(\varepsilon_c^2 - \varepsilon_s^2)} \]

\[ \times (\mu_C^{0c})_j(\hat{R}_{AC})_k + (\mu_C^{0c})_i(\hat{R}_{AC})_k \]

\[ - 5(\mu_C^{0c})_i(\hat{R}_{AC})_j(\hat{R}_{AC})_k \]  

(49)

The octant rule follows from Equation (49) when we reduced our consideration to the term that has an isotropic polarizability component (the octant rule term), i.e. set \( k = z \) and ignore the first two terms in the final brackets. As noted above, there are occasions when the octant rule is not appropriate because other terms in Equation (49) (or even higher order terms in the \( V \) expansion) become dominant.

Equation (49) after appropriate symmetry averaging also leads to the CD expressions for degenerately \( x, y \)-polarized transitions of molecules with \( D_{2d} \) A (Figures 7 and 8), since the A moment product of Equation (49) does not vanish for these polarizations under this symmetry. Take \( z \) to be the three-fold rotation axis and \( x \) to align with one of the two-fold rotation axes of A. By symmetry, the only nonvanishing A moment products are those in Equation (50) so the \( E \)-polarized tris chelate transition metal complex CD is:\(^{(20)}\)

\[ R \left( D_{2d}, \frac{x}{y} \right) = -\text{Im} \frac{3\varepsilon_c}{4R_{AC}^4(\varepsilon_c^2 - \varepsilon_s^2)} \]

\[ \times \delta_{ij} (Q_A^{10})_{jk} - (Q_A^{10})_{ij}(m_A^{01})_k \]

\[ - 2(Q_A^{10})_{ij}(m_C^{01})_k \]

\[ + 2(\mu_C^{0c})_i(\hat{R}_{AC})_j - 5(\mu_C^{0c})_k \]

\[ \times (\mu_C^{0c})_j(\hat{R}_{AC})_k \]

\[ - 4(\mu_C^{0c})_i(\mu_C^{0c})_j(\hat{R}_{AC})_k \]

\[ + 10(\mu_C^{0c})_k \]

\[ \times (\mu_C^{0c})_j(\hat{R}_{AC})_k \]

\[ - 4 [ (Q_A^{10})_{jk} - (Q_A^{10})_{ij} ] (m_A^{01})_k \]

\[ \times (\mu_C^{0c})_i(\mu_C^{0c})_j(\hat{R}_{AC})_k \]

\[ + (\mu_C^{0c})_k(\hat{R}_{AC})_k \]

\[ - (\mu_C^{0c})_k(\hat{R}_{AC})_j \]

\[ \times (\mu_C^{0c})_j(\hat{R}_{AC})_k \]  

(50)
Equation (51) is the basis of the above discussion of $E_g$ polarized $d-d$ transitions of tris-chelate metal complexes.

When A has higher than two-fold rotational symmetry, then the quadrupole–dipole term of Equation (50) is zero for transitions polarized along the high symmetry rotation axes (e.g. for A2 polarized transitions of tris-chelates). Since the octupole term in the $V$ expansion also vanishes under these circumstances$^{(20)}$, the term in the $V$ expansion for A2 polarized transitions is the hexadecapole–dipole term which has an $R_{4AC}$ dependence so is smaller than the $E_g R_{4AC}^2$ term; hence the dominant E band rule discussed above.

2.5 Circular Dichroism of Electric Dipole Allowed Transitions

For EDA transitions, the independent systems approach leads to mechanisms that are usually referred to as coupled-oscillator models. Because we choose to use perturbation theory to give expressions for wavefunctions (as discussed above), we need to consider identical and nonidentical [A,C] systems separately.

2.5.1 Identical A and C: the Degenerate Coupled Oscillator Model

Most transitions for which we measure UV/VIS absorbance spectra are EDA. If an EDA transition, with EDM $\mu_{ac}^{(0)}$ and transition energy $\varepsilon$, of an achiral chromophore, A, has a measurable CD spectrum, then it must have "borrowed" some magnetic character to give a net helical electron rearrangement. The degenerate coupled-oscillator model describes the situation where A and C are identical and the magnetic character comes from the coupling of $\mu_{ac}^{(0)}$ with the same energy EDM in C, $\mu_{ac}^{(0)}$. $\mu_{ac}^{(0)}$ must be oriented skew relative to $\mu_{ac}^{(0)}$ for a CD signal to be observed near $\varepsilon$. $\mu_{ac}^{(0)}$ induces a magnetic effect in A since, although it is a linear motion of charge within C, when viewed from A it moves (circles) around A’s origin ($\mu_{ac}^{(0)}$) simultaneously induces a magnetic component into the C transition $\mu_{ac}^{(0)}$.

In this case, where A and C are identical, by symmetry (or degenerate perturbation theory) the two states that result from the mixing of $|10\rangle$ (A in |1) and C in the ground state) and $|01\rangle$ are given by Equation (52)$^{(3-5,32)}$

$$|10\rangle = \frac{1}{\sqrt{2}}(|10\rangle \pm |01\rangle) \quad (52)$$

where the $|10\rangle$ state takes the upper sign of the ± or ± terms in this equation and those that follow. As above, we use real normalized wavefunctions. If we also assume that permanent moments are much smaller than transition moments, then the energies of these two states are, Equation (53)$^{(3-7,32)}$

$$\varepsilon^\pm = \langle 10\rangle |HA + HC| \mp V|10\rangle$$

$$\frac{1}{2}|10\rangle + (0)HC|01\rangle \pm (10)|V|01\rangle$$

$$\varepsilon^0 + \varepsilon^1 \pm V^{10,01} = \varepsilon \pm V^{11} \quad (53)$$

where, for example, Equation (54)

$$V_{ba,dc} = (ac)|V|bd$$

$$= (\mu_{bc}^{(0)} - 3\mu_{ac}^{(0)}\mu_{ac}^{(0)}\mu_{ac}^{(0)} + \text{higher order terms}) R_{4AC}^2 \quad (54)$$

Because all wavefunctions are real, when one state on each of A and C is the ground state we further simplify the notation as indicated in the last line of Equation (53). $V^{11}$ is much smaller than $\varepsilon$ so the two new perturbed states are close in energy.

The EDM for the transitions from the two excited states of Equation (52) to the ground state |00⟩ are, Equation (55):

$$\langle 00|\mu_{ac}^{(0)}|10\rangle = \frac{1}{\sqrt{2}}(|00|\mu_{ac}^{(0)} + \mu_{ac}^{(0)}[|10\rangle \pm |01\rangle]) \quad (55)$$

The $|0\rangle \rightarrow |1\rangle$ transitions in both A and C are MDF, and so have no intrinsic magnetic moment. We therefore set $\bar{m}_A = \bar{m}_C = 0$ in Equation (35). The momenta MDM terms are more conveniently dealt with when re-expressed in terms of EDMs for the appropriate transition exploiting a very useful relationship$^{(32)}$, Equation (56)

$$(k|\bar{p}_C|j) = \frac{im_c}{\varepsilon_h}(\varepsilon_k - \varepsilon_j)\mu_{C}^{ik} \quad (56)$$

from which follows Equation (57)

$$m_{C}^{ik} = (k|\bar{m}_C|j) = \frac{e}{2m_c}(k|\bar{R}_C\bar{p}_C|j)$$

$$= \frac{i}{2h}\bar{R}_C(\varepsilon_k - \varepsilon_j)\mu_{C}^{ik} \quad (57)$$

This is the magnetic moment at the origin (0,0,0) created by the tangential EDA transition moment $\mu_{C}^{ik}$. The
MDTs for the return transition from to the ground state to the perturbed excited states are then, Equation (58)

\[
(10 \pm i|\tilde{m}|00) = \frac{ie}{\sqrt{8\hbar}} \left\{ R_{A}\mu_{A}^{01} \pm R_{C}\mu_{C}^{01} \right\}
\]

Substituting Equations (55) and (58) into the Rosenfeld equation (Equation 30b) gives the CD strengths of bands centered at \(\epsilon^+\) and \(\epsilon^-\) (Equation 53) arising from the coupling of degenerate \(|0\rangle \rightarrow |1\rangle\) transitions on A and C to be, \(E^8\) Equation (59)

\[
R_{\pm}^{01} = \frac{\pm e}{4\hbar} \left\{ \mu_{C}^{01}R_{A}\mu_{A}^{01} \epsilon_{C} - R_{A}\epsilon_{A} \right\}
\]

where the ‘+’ transition is not necessarily higher in energy than the ‘−’ transition.

The physical interpretation and applications of Equation (59) for solving geometric and spectroscopic problems is most easily seen by choosing the coordinate system illustrated in Figure 14 in which case Equation (59) may be written, Equation (60):

\[
R_{\pm}^{01} = \frac{\pm e}{4\hbar} R_{AC}^{01} \sin \alpha \sin \gamma \sin \tau
\]

and the energies of the two bands are, Equation (61)

\[
\epsilon^{\pm} = \epsilon \pm \mu^{2} \left( \sin \alpha \sin \gamma \cos \tau + 2 \cos \alpha \cos \gamma \right)
\]

where \(\mu\) is the magnitude of \(\mu_{A}\) and \(\mu_{C}\).

The expected CD spectrum for two degenerate chromophores as a function of \(\tau\) is illustrated in Figure 15. Because independent systems theory is identical to the theory of exciton particles, these degenerate coupled systems are often referred to as exciton CD spectra.

2.5.2 Different A and C: Nondegenerate Coupled Oscillator Circular Dichroism

When A and C are not identical then the wavefunctions of the A/C system follow from nondegenerate perturbation theory, \(E^5-E^3\) We may write Equations (62) and (63)

\[
|00\rangle = |00\rangle - \frac{(1c|V|00)}{\epsilon_{C} + \epsilon_{A}}|1c\rangle
\]

\[
|10\rangle = |10\rangle - \frac{(0c|V|10)}{\epsilon_{C} - \epsilon_{A}}|0c\rangle
\]

The EDTM of the perturbed \(|10\rangle \rightarrow |00\rangle\) transition is given by Equation (64)

\[
\mu^{10} = \langle 00|\tilde{m}|10\rangle = \langle00|\mu_{A}\rangle10 - \langle00|\mu_{C}\rangle0c
\]

\[
= \langle 00|\mu_{A}\rangle10 - \langle 00|\mu_{C}\rangle0c \left( \frac{0c|V|10}{\epsilon_{C} + \epsilon_{A}} - \frac{0c|V|10}{\epsilon_{C} - \epsilon_{A}} \right)
\]

Similarly, \(E^8\) Equation (65)

\[
m^{01} = \langle 10|\tilde{m}|00\rangle = \frac{e}{2m_{e}} \left\{ R_{AC}^{01} - \frac{2\epsilon_{A}V_{1c}}{\epsilon_{C}^{2} - \epsilon_{A}^{2}}R_{C}\mu_{C}^{0c} \right\}
\]

\[
= \frac{i}{2\hbar} \left\{ \epsilon_{A}R_{A}\mu_{A}^{01} - \frac{2\epsilon_{A}V_{1c}}{\epsilon_{C}^{2} - \epsilon_{A}^{2}}R_{C}\mu_{C}^{0c} \right\}
\]

since the transition has no intrinsic magnetic moment within A as in the case of the degenerate coupled oscillator model.

The CD strength is therefore, Equation (31) \(E^8\)

\[
R(|00\rangle \rightarrow |10\rangle) = \frac{-\epsilon_{A}V_{1c}}{\hbar(\epsilon_{C} - \epsilon_{A})} \times \left\{ \mu_{C}^{01}R_{AC}^{0c} + \mu_{C}^{01}R_{AC}^{0c} \right\}
\]

\[
= \frac{-\epsilon_{A}\epsilon_{C}V_{1c}}{\hbar(\epsilon_{C} - \epsilon_{A})^{2}} \left\{ \mu_{C}^{01}R_{AC}^{0c} \right\}
\]

Figure 14 Diagram illustrating the geometry and coordinates for an A/C system. Note that \(\tau\) is the angle taken in the anticlockwise direction between the projections of the EDTMs onto the \(y-z\) plane when the observer is looking down the \(x\)-axis. \(0^\circ < \tau < 180^\circ\) if \(\mu^x \times \mu^y R_{AC} > 0\) (i.e. if the three vectors form a right-handed parallelepiped), and \(180^\circ < \tau < 360^\circ\) if \(\mu^x \times \mu^y R_{AC} < 0\). CAR right-handed summarizes a mnemonic for the situation where \(\mu^x, \mu^y,\) and \(R_{AC}\) form a right-handed axis system with \(0^\circ < \tau < 180^\circ\).
Again using the coordinate system defined in Figure 14 we may write Equation (67)
\[
R(\varepsilon_a) = \frac{-\varepsilon_a \varepsilon_c (\mu_a \mu_c)^2}{\hbar (\varepsilon_c^2 - \varepsilon_a^2) R_{AC}} \left[ \sin \alpha \sin \gamma \cos \tau + 2 \cos \alpha \cos \gamma \right] 
\times \sin \alpha \sin \gamma \sin \tau
\]
which is usually easier to implement than Equation (66).

3 LINEAR DICHROISM

3.1 Introduction
LD is the difference in absorption of light linearly polarized parallel and perpendicular to an orientation axis, Equation (68):

\[
LD = A_\parallel - A_\perp
\]

LD is related to CD in that both require the difference between the absorbances of different polarized light beams to be measured and CD spectropolarimeters can be adapted to produce the required alternating beams of polarized light for LD. However, LD measurements are performed on systems that are either intrinsically oriented or are oriented during the experiment (Figure 16). The general LD references given below may be consulted for more details on the definitions and equations that follow. Rodger and Nordén use the formalism adopted here.

The equations for LD were given in Equations (22) and (23) in the context of the interaction of radiation with matter. In order to understand LD more fully, consider what happens when a molecule absorbs a photon: absorption can be pictorially viewed as either the electric field or the magnetic field (or both) of the radiation pushing the electron density from a starting arrangement to a higher energy final one. The direction of net linear displacement of charge is known as the polarization of the transition. The polarization and intensity of a transition are characterized by the EDTM (see Equations 18 and 19) which may be regarded as the antenna by which the molecule absorbs light. Each transition thus has its own antenna and the maximum probability of absorbing light is obtained when the antenna and the electric field of the light are parallel.

Now imagine a linearly polarized light beam (Figure 16) and a sample of molecules all oriented in exactly the same way. If the normal absorption is first measured with the light polarized so that it is parallel to the direction of orientation of the sample and then measured when the light is polarized perpendicular to this direction, the difference between these two spectra is the LD spectrum. The two extreme situations are:

![Figure 15](image-url) Exciton CD spectra for coupling ‘short-axis’ polarized transitions. (a) Illustrates characteristic form that results from cancellation of overlapping bands; - - - -, higher energy component; , lower energy component; , observed CD spectrum. (b) Illustrates the geometry of the system. (c) Shows the net spectra as a function of \(\tau\) (assuming Gaussian band shapes for the two transitions).
1. If the polarization of the transition that is being probed is perfectly parallel to the orientation direction, then Equation (69) follows

\[ LD = A_\parallel - A_\perp = A_\parallel > 0 \] (69)

2. If the polarization of the transition that is being probed is perpendicular to the orientation direction, then Equation (70) follows

\[ LD = A_\parallel - A_\perp = -A_\perp < 0 \] (70)

For intermediate polarizations, the LD is between these cases. Thus, the polarization for a given transition can be determined from its LD spectrum if the orientation of the molecule is known; conversely, LD can be used as a probe of molecular orientation if the polarization of a transition moment within the molecule is known. In practice, one type of experiment is often performed, followed by the other, using different orientation methods.

The two extreme cases of Equations (69) and (70) are both illustrated in the simplified anthracene spectrum of Figure 17. The spectrum is simplified in two ways:

1. perfect orientation of the molecules has been assumed, and
2. the long wavelength band has been assumed to be of pure short-axis polarization.

In reality perfect orientation is never achieved and there is a significant long-axis polarized component at \( \sim 320\, \text{nm} \) due to coupling with the 250 nm band.

### 3.2 Orientation Parameters

A variety of different orientation methods for LD spectroscopy are outlined below. In practice, with the possible exception of a crystalline environment, the orientation is never perfect and we need to use the concept of an orientation distribution. In many cases, either the averaging inherent in the orientation method or the nature of the sample means that (at least) local uniaxial orientation can be assumed (Figure 18) and the simple orientation parameter \( S \) can be used. Equation (71) is then valid

\[ LD' = \frac{LD}{A} = \frac{A_\parallel - A_\perp}{A} = \frac{3}{2} S(3 \cos^2 \alpha - 1) \] (71)

\( LD' \) is the so-called reduced LD, \( S \) may be viewed as a scaling factor defining the efficiency of macroscopic orientation, and \( \alpha \) is an angle that specifies the orientation of the transition moment that is responsible for the absorption of light at the particular wavelength (if several transitions absorb at the same wavelength an average is obtained) with respect to the orientation axis (Figure 19). \( S = 1 \) for perfect orientation and \( S = 0 \) for random (i.e. no) orientation. In Equation (71) \( A \) is the absorption of the LD sample under isotropic (unoriented) conditions so \( A_1, A_\perp, \) and \( A \) all have \( Cl \) as a common factor, hence when using \( LD' \) it is not necessary to know the sample concentration or path length. If the sample is macroscopically as
Uniaxial orientation requires all orientations on a cone about the orientation axis to be statistically equally probable. This may be due to static or dynamic factors.

Macroscopic and molecular axes systems and angles relating them.

Well as molecularly uniaxial, such as molecules oriented in a polymer film drawn in one direction or polar molecules in an electric field, there is a simple relation between \( A_{ij} \) and \( A \), which makes it unnecessary to measure all three quantities, Equation (72):

\[
A = \frac{1}{2}(A_{||} + 2A_{\perp})
\]

When the orientation method used in an LD experiment provides a uniaxial sample (Figure 18) and the sample molecules are also characterized by a unique axis around which all orientations are equally probable (so the molecule is ‘rod-like’), we may then write, Equation (73):

\[
S = \frac{1}{2}(3(cos^2 \theta) - 1)
\]

where \( \theta \) is the angle between the macroscopic orientation direction \( Z \) and the molecular orientation axis \( z \) (Figure 19). \( \theta \) is used instead of \( \zeta \), to which the same definition is given below, as a reminder that Equation (73) only holds for rod-like molecules in uniaxial samples. It is important to note that the averages of \( (cos^2 \theta) \) are appearing in the above equations. These are not the same as the \( (cos^2) \) of (average angles), though in practice we usually have to ignore what can be a considerable difference.

More generally, instead of a single orientation parameter we need to have three since in some LD experiments, including rectangular squeezing of a gel or when the light is incident radially upon a cylindrical couette flow cell (Figure 20), the system behaves as if the orientation were biaxial (Figure 18) for which the constant probability contour for a given molecular axis traces out an ellipse. (Note: flow-oriented DNA, see below, is uniaxially oriented due to the helical nature of the molecule.) A laboratory (macroscopic) axis system \( \{X, Y, Z\} \) is defined first, such that \( X \) is the direction of propagation of the incident radiation and \( Z \) is the macroscopic direction of orientation. \( Y \) then completes the right-handed axis system. The more general definition of LD is then, Equation (74)

\[
LD = A_Z - A_Y
\]

(cf. Equation 23). Similarly, we write Equation (75)

\[
LD^x = 3 \left( \frac{A_Z - A_Y}{A_X + A_Y + A_Z} \right) = 3((\mu_Z^2) - (\mu_Y^2))
\]

When studying LD it is also convenient to define the molecular axis system, \( \{x, y, z\} \). We take \( z \) to be the molecular orientation axis, i.e. the axis in the molecule which has maximum value shown by Equation (76) of

\[
(cos^2 \zeta)
\]

where \( \zeta \) is the angle between \( z \) and \( Z \). \( x \) is the axis perpendicular to \( z \) that has the smallest value shown by Equation (77) of

\[
(cos^2 \xi)
\]

where \( \xi \) is the angle between \( x \) and \( Z \). \( \psi \) is similarly the angle between \( y \) and \( Z \). \( z \) is often, but not always, the highest order symmetry determined axis.

The general definitions of the orientation parameters are given by Equation (78)

\[
S_{xx} \ S_{xy} \ S_{xz} \\
S_{yx} \ S_{yy} \ S_{yz} \\
S_{zx} \ S_{zy} \ S_{zz}
\]

where

\[
\begin{pmatrix}
\frac{1}{2}(3(cos^2 \xi) - 1) & 0 & 0 \\
0 & 0 & \frac{1}{2}(3(cos^2 \xi) - 1)
\end{pmatrix}
\]

(78)
Since we defined $z$ to be the most oriented molecular axis, and $x$ to be the least oriented, Equation (79) follows:

$$S_{zz} \geq S_{yy} \geq S_{xx}$$  \hspace{1cm} (79)

Further, the trace of the orientation tensor is zero so that, Equation (80):

$$S_{xx} + S_{yy} + S_{zz} = 0$$  \hspace{1cm} (80)

For rod-like molecules $S_{xx} = S_{yy}$ and $S$ for the uniaxial case is $S_{zz}$.

In solving any particular problem, the positions of $\{x, y, z\}$ are seldom known, so it is usually convenient first to choose a temporary molecular axis system $\{x', y', z'\}$ which probably bears no relationship to the orientation axis system but is convenient for our analysis (see example below). Analogously to the definitions we used with the ‘true’ molecular axis system, the orientation of the macroscopic orientation axis $Z$ in the new coordinate system may then be written, Equation (81), as the vector

$$(\cos \xi', \cos \psi', \cos \zeta')_{x'y'z'}$$  \hspace{1cm} (81)

also, Equation (82)

$$S' = \begin{pmatrix} S_{xx'} & S_{xy'} & S_{xz'} \\ S_{yx'} & S_{yy'} & S_{yz'} \\ S_{zx'} & S_{zy'} & S_{zz'} \end{pmatrix}$$

$$= \frac{1}{2} \begin{pmatrix} 3(\cos^2 \xi') & 3(\cos \xi' \cos \psi') & 3(\cos \xi' \cos \zeta') \\ 3(\cos \xi' \cos \psi') & \frac{1}{2}(3(\cos^2 \psi')) & 3(\cos \psi' \cos \zeta') \\ 3(\cos \xi' \cos \zeta') & 3(\cos \psi' \cos \zeta') & \frac{1}{2}(3(\cos^2 \zeta')) \end{pmatrix}$$

(82)

For planar molecules in uniaxially oriented systems, $x' = x$ so $\xi' = \xi$. It follows that $\{x', y', z'\}$

$$LD' = 3(S_{yy'} \sin^2 \alpha' + S_{zz'} \cos^2 \alpha' + S_{zy'} \sin \alpha' \cos \alpha')$$

(83)

where $\alpha'$ is the angle between the transition dipole moment and axis $z'$. The three orientation parameters in Equation (83) are three unknowns, so three different transitions of known polarization are needed to determine them. The position of $z$ is almost determined from
Equation (84)\(^{(8,34)}\)
\[
\tan(2\beta) = \frac{S_{yz}}{S_{zz'} - S_{yz'}}
\]  
\(\text{(84)}\)

where \(\beta\) is the angle between \(z'\) and \(z\). Either chemical intuition or another experiment such as fluorescence polarization anisotropy\(^{(35)}\) is required to determine on which side of \(z'\), \(z\) lies. It is often apparent upon inspection.

### 3.3 Molecular Alignment Techniques

In addition to the requirement of linearly polarized light for LD, LD experiments are made technically demanding because of the need to orient the sample. The orientation method used for this depends on the sample. Long polymers may be oriented by shear flow whereas small molecules require a stronger orienting force. A selection of orientation methods is described below. More details may be found in the general LD references.

#### 3.3.1 Stretched Polymers

Small molecules can often be absorbed into polymer films, usually polyethylene or poly(vinyl alcohol) (both can be used well into the UV even down to 200 nm) depending on the polarity of the analyte. When the film is mechanically stretched, either before or after the small molecules are added, the absorbed molecules align their long axes preferentially along the stretch direction (Figure 17). There has been no evidence that a solute is better oriented when introduced into the film before stretching compared with it being added after stretching; with poly(vinyl alcohol); however, the film is usually cast containing the analyte so it cannot be added after stretching.

#### 3.3.2 Flow Orientation

Long polymers may be oriented by the viscous drag caused when a solution is flowed between narrow walls.\(^{(36)}\) Depending on the cell design, the light is then propagated either along the flow direction or perpendicular to it. This technique is commonly used for LD studies of DNA (the DNA needs to be at least of the order of 1000 base pairs in length to get significant orientation). The most successful flow cell has proved to be a cylindrical couette flow cell where the solution containing the DNA is subjected to a constant gradient over the annular gap between two coaxial cylinders one of which is rotating (Figure 20).

#### 3.3.3 Electric Field Orientation

Effective uniaxial orientation for polar or polarizable molecules (including DNA since its ionic environment is polarizable) may be achieved by an electric field between two parallel plates.\(^{(37)}\) Electric orientation is conceptually simpler than flow orientation, and the data can be fairly easily extrapolated to infinite orientation which contrasts with the situation for flow orientation. Heating effects may be circumvented by using pulsed field techniques, which additionally enable the study of relaxation phenomena. However, the pulsed nature of the field generally requires each electric dichroism experiment to be performed at a fixed wavelength or else a diode array system to be used; it is also usual to measure \(A_1\) and \(A\) (the unoriented absorbance) rather than \(A_{\perp}\) (as the orientation is uniaxial, only two of the three absorbances need be determined independently as discussed above).

#### 3.3.4 Squeezed Gel Orientation

The method of orientation that has proved most successful for membrane proteins, particularly photosynthetic ones, is to embed the protein in a gel (usually polyacrylamide) and then physically squeeze the gel either unidirectionally or bidirectionally (Figure 21).\(^{(28)}\) The main shortcomings of the gel orientation technique are its limitation to wavelengths longer than 250 nm, and the limited dynamic range of deformation.

#### 3.3.5 Migrative Orientation

While migrating in an electrophoresis gel, DNA is macroscopically oriented and gives an LD signal.

#### 3.3.6 Magnetic Field Orientation

Magnetic fields may be used to orient molecules in much the same way as electric fields, however, the effect is small and this method is not widely used unless the particles are large (such as chloroplasts) and carry substantial magnetic dipole moments.

![Figure 21 Principles of biaxial and uniaxial squeezing of gels.](image)
3.3.7 Crystalline Samples
If the absorbance is not too large for the spectrometer to measure, crystals may be used for LD studies.

3.3.8 Liquid Crystal Orientation
The molecules within a liquid crystal are oriented with respect to one another and by sandwiching the liquid crystal between two quartz plates, macroscopic orientation may be achieved. The sample must be tilted with respect to the light beam to get an LD signal. Molecules dissolved in a liquid crystal may also have a preferential orientation.

3.3.9 Orientation by Evaporation, for Example onto Quartz
This method may be appropriate for some samples, particularly planar aromatic molecules that readily adsorb onto quartz. The quartz plate has to be tilted for LD measurement.

3.4 Examples of Linear Dichroism Data
3.4.1 DNA
The absorption, and hence LD, spectra of nucleic acids in the easily accessible UV region of the spectrum (down to 180–190 nm) are dominated by the $\pi \rightarrow \pi^*$ transitions of the purine and pyrimidine bases which, by symmetry, are all polarized in the plane of the bases. If DNA is in the idealized B-DNA form with the DNA bases perpendicular to the helix axis then a flow oriented DNA sample (Figure 20) should have its LD across the whole spectrum constant and negative. In practice, there is some variation in magnitude (Figure 22) which indicates that the bases are tilted.

Normal B-DNA, which according to the classical fiber structure has $\theta_X = -2.1^\circ$ and $\theta_Y = 4.0^\circ$ (Figure 23, though fiber B-DNA has 10 base pairs per turn of the helix rather than the 10.4–10.6 of solution DNA), should display only small variations in LD in the wavelength region 230–300 nm with $\text{LD}^\prime/S = -1.47 \pm 0.02$. A-form DNA, with $\theta_X = 19.3^\circ$ and $\theta_Y = -3.2^\circ$, is, however, expected to exhibit a sloping LD, with $\text{LD}^\prime/S$ varying from about $-1.2$ at 230 nm to about $-1.4$ at 300 nm, depending on the sequence of the DNA. Z-DNA is longer and stiffer and so is expected to have a significantly larger LD signal than the same sequence of B-DNA as shown in Figure 22.

LD data has been analyzed to determine the average values for base roll, tilt, twist, and slide for the different DNA bases in solution B-DNA; a value of $\alpha = 73^\circ$ is appropriate for purines, whereas $\alpha = 65^\circ$ for pyrimidines. These results are dependent on the accuracy of the assignment of base transition polarizations, intensities, and bandwidths. An effective average value of $84^\circ$ for $\alpha$ at 260 nm is often assumed for B-DNA based on the fiber diffraction structure and an estimate of contributions from different transitions to the total LD.

3.4.2 Linear Dichroism of DNA-bound Ligands
Once the orientation of DNA itself is understood a next step is to use LD to probe the binding and orientation
CIRCULAR DICHROISM AND LINEAR DICHROISM

Figure 23 Geometry parameters for DNA as used in the text.

on DNA of small ligand molecules and even proteins. A key feature of such LD studies is that if there is no specific binding, then there will be no LD of the ligand transitions. Conversely, the presence of an LD signal from an absorption band of the putative ligand immediately implies that it is bound. Although LD cannot tell us where a ligand binds to DNA, it can be used to determine the orientation of the ligand on the DNA (if the ligand’s transition moments have been assigned). This often provides significant clues as to the binding mode. A ligand may bind to DNA in a number of different types of site, as well as with sequence and orientation preferences.

Broadly speaking a ligand may bind in the following ways.

1. **Externally** bound to the phosphate backbone: this is usually orientationally fairly nonspecific and the induced LD (and CD) is correspondingly small.

2. **Intercalated** between DNA bases: this mode requires planar aromatic molecules and the DNA to unwind and open up a slot between adjacent base-pairs so the ligand may be sandwiched between them. The DNA is stiffer and locally better oriented near the intercalation site, so the LD of an intercalator is usually slightly larger (more negative) at 260 nm than that of the average DNA base. If the bases are tilted, then the intercalator follows that tilt and this may be apparent in the LD. For example, the short axis of 9-hydroxyellipticine aligns with the long axis of the base-pair pocket and has a slightly smaller LD signal than the long axis of the molecule which is perpendicular to the pocket and also more perpendicular to the helix axis than the base pairs (Figure 25).

3. In the **minor groove**: this mode is frequently adopted by aromatic molecules containing internuclear bonds with some rotational freedom. For example, long molecules such as netropsin, distamycin, Hoechst 33258, and 4′,6-diamidino-2-phenylindole (Figure 24), which can fit snugly into the minor groove with the molecule following the curvature of the groove but are too large to fit into an intercalation site, favor this mode of binding. The long axis of

Figure 24 The intercalators (a) ethidium bromide and (b) 9-hydroxyellipticine, and some minor groove binders: (c) netropsin, (d) Hoechst 33258, and (e) 4′,6-diamidino-2-phenylindole.
ELECTRONIC ABSORPTION AND LUMINESCENCE

Figure 25 Some examples of LD spectra for DNA bound ligands. (a) 9-Hydroxyellipticine (1–10 µM in 2.5 µM increments, signal increases with ligand concentration) with 100 µM calf thymus DNA in NaCl (20 mM) and phosphate buffer (1 mM, pH 7);(41,45,46) (b) trans-bis-(4-N-methylpyridiniumyl)diphenylporphyrin (5 µM) with 40 µM calf thymus DNA in phosphate buffer (1 mM, pH 7) and varying NaCl concentrations (see figure insert) showing the change in binding orientation as a function of ionic strength. Signal increases with ligand concentration.

4. In the major groove: this type of binding is found for several regulatory proteins and there is enough space to accommodate most smaller ligands in a variety of orientations.

Some examples of LD spectra for DNA bound ligands are given in Figure 25.

3.4.3 Determination of the Molecular Orientation Axis of a Molecule in a Stretched Film

Infrared LD is particularly useful for determining orientations, particularly of small molecules in stretched films, because the polarization of vibrations are often known simply from their position in the spectrum. For example, riboflavin has three infrared bond stretching vibrations.(35) For convenience we choose the primed axis system as illustrated in Figure 26. The values of the LD$^\prime$ for each transition are also given in Figure 26.

For the three transitions for which the data is given in Figure 26, Equation (83) leads to Equation (85)

$$
+0.070 = 3(S_{\alpha'}+0.970S_{\alpha''}+0.174S_{\alpha''})
$$

$$
+0.800 = 3(0.030S_{\alpha'}+0.750S_{\alpha''}+0.433S_{\alpha''})
$$

From which Equation (86) follows

$$
S_{\alpha'} = 0.024 \quad S_{\alpha''} = 0.256 \quad S_{\alpha''} = 0.373
$$

Thus, $\beta$ (Equation 84) either equals 61° or 151°. By inspection of Figure 26, we conclude that $\beta = 61°$ is correct and the dashed line of Figure 26 is the molecular orientation axis $z$.

4 INSTRUMENTATION AND THE DICROISM EXPERIMENT

4.1 Circular Dichrographs (Spectropolarimeters)

The essential features of a CD spectropolarimeter are a source of (more-or-less) monochromatic left and right circularly polarized light and a means of detecting the difference in absorbance of the two polarizations of light. The normal method of achieving these requirements, because the CD of molecules is generally quite weak compared with the total absorbance signal, is to implement a polarization phase-modulation technique. A photelastic modulator (PEM) (in older instruments a Pockels cell) produces alternatively right and left circularly polarized light.

Figure 26 Riboflavin indicating the temporary axis system used in the calculation and the polarizations and LD$^\prime$ values for the three transitions used in the text. Data are from Matsuoka and Nordén. (34)
light. The light intensity is constant, but upon passage through a sample exhibiting CD an intensity fluctuation (corresponding to the different absorptions of left and right circularly polarized light) that is in phase with the modulator frequency appears. The unabsorbed photons hit a photomultiplier tube which produces a current whose magnitude depends on the number of incident photons.

The light source in most CD instruments is a xenon arc lamp for UV and visible CD measurements. This means that the instrument has most sensitivity in the 300–400 nm region of the spectrum. The fact that a lamp is getting old becomes apparent by decreased light intensity in the 200 nm and 700 nm regions of the spectrum. The optics of a typical CD machine are illustrated in Figure 27. A series of mirrors and prisms and slits are used to produce collimated monochromatic radiation (in reality it is not monochromatic but has a well-defined wavelength range, typically of 0.5–2 nm). This light is then linearly polarized and subsequently circularly polarized. The conversion of linearly polarized light into circularly polarized light is achieved by the PEM.

The PEM consists of a piece of crystal quartz mechanically coupled (glued) to a piece of isotropic (silica) quartz, the light passing through the latter. The quartz plate is oriented so that light polarized (say) vertically travels through it at one speed and light polarized horizontally travels more slowly. If the linearly polarized light is incident on the plate at a 45° angle, then it may be considered as split into equal magnitude vertical and horizontal components. The PEM exhibits birefringence so that \((n_Z - n_Y) \neq 0\), i.e. the refractive indices \(n_Z\) and \(n_Y\) for vertical and horizontal polarizations are different. During passage through the PEM the phase difference between the vertical and horizontal light beam components will amount to, Equation (87):

\[
\delta = \frac{2\pi D}{\lambda} = \frac{2\pi d(n_Z - n_Y)}{\lambda}
\]

where \(d\) is the thickness of the PEM, \(\lambda\) is the wavelength of the light, and \(D\) is the path difference between the light components. At a certain value of \((n_Z - n_Y)\), \(\delta\) will be equal to \(\pi/2\) and \(D\) equal to \(\lambda/4\), making the so-called ‘quarter wave’ plate required to produce circularly polarized light.

An ac (alternating current) voltage is applied to the crystal part, causing the whole PEM assembly to oscillate (typically at 50 kHz). By adjusting the voltage amplitude so that the birefringence amplitude corresponds to the quarter wave condition at each \(\lambda\), the time dependence of \((n_Z - n_Y)\) as it oscillates between \(+|n_Z - n_Y|\) and \(-|n_Z - n_Y|\) gives light that is alternately left and right circularly polarized. The polarized light thus produced then passes through the sample compartment (and the sample) and what is not absorbed is detected by the photomultiplier tube. If the sample has no CD the photomultiplier current will be a constant, direct current (dc) with a magnitude determined by the normal absorbance of the sample. If the sample exhibits CD

![Figure 27](image_url)
the photomultiplier current will also show an oscillating component (ac). The CD is obtained as the ratio between the ac and dc components. Its sign is determined from the phase of the ac component using a lock-in amplifier that has the ac voltage of the PEM as a time reference.

With both DNA and protein CD experiments it is important to think carefully about the buffer to be used. CD instruments are single beam spectrometers and so there is no automatic compensation mechanism for buffer absorbance as there is for normal absorbance spectroscopy where the buffer can be placed in a reference cuvette. Many CD experiments fail or give nonsense results as all the light is absorbed by the nonchiral parts of the solution.

4.2 Design and Implementation of an Linear Dichroism Experiment

The components of an LD experiment are a source of linearly polarized light, a means of detecting how much light is absorbed, a method of orienting the sample (as discussed above), and a way to change the relative orientations of sample and light beam. There are two main methods for measuring LD spectra. The one requiring less specialized equipment is the two-spectra method. Using a double beam spectrophotometer equipped with a polarizer (e.g. of Glan type) which is not sensitive to beam divergence, the sample is oriented parallel to the polarization direction of the polarizer to obtain \( A_1 \). It is then oriented perpendicular to the polarization direction of the polarizer to obtain \( A_\perp \). (Alternatively, the polarizer may be rotated, in which case any effect of internal polarization of the light by the optics of the spectrometer must be considered.)

The other method, the differential method, is much easier to implement and a wider range of sample orientation techniques may be used. However, much more sophisticated instrumentation is required as the phase-modulation technique of a circular dichrometer is used, either by supplementing the latter with a quarter wave device (e.g. a Fresnel rhomb or an Oxley prism to achieve achromacy\(^{(3–7)}\)) or by increasing the driving voltage of the PEM and doubling the beat frequency of the lock-in amplifier. A factor of two increase in the voltage across the quarter wave PEM that turns linearly polarized light into alternating left and right circularly polarized light for CD measurements, turns the PEM into a half-wave plate that produces alternating pulses of orthogonal beams of linearly polarized light for LD spectroscopy. The differential method has the advantage of being extremely sensitive, needing only very low sample orientation or concentration.

1 General Detector Requirements and Performance Characteristics

Commercial absorption and luminescence detectors can vary widely in terms of their sensitivity, spectral response, response time, linearity and signal-to-noise ratios (S/Ns). Specific analytical applications often dictate the minimum performance characteristics that the radiation detector can possess. For example, in the case of a photomultiplier tube (PMT) the minimum requirements for measuring fluorescence lifetimes by both pulse and phase-modulated methods include: (1) fast time-response of typically 1.5 ns risetime, (2) electron gains exceeding 5 million, (3) low noise of less than 100 counts s\(^{-1}\), (4) low transit-time dispersion with point of illumination on the cathode (i.e. <20 ps mm\(^{-1}\)), and (5) low afterpulsing from ion or photon feedback to the photocathode and low repulsing from photoelectron generation at the dynodes. The characteristics given below are commonly employed in evaluating the different absorption and luminescence detectors for a particular analytical application.

Response time is the measure of the detector’s ability to detect rapid changes in the incident radiant power. Quantitatively, the response time is evaluated in terms of the time constant \(t_D = \frac{1}{2\pi f_c}\), where \(f_c\) is the frequency at which the incident radiant power has fallen to 0.707 of its maximum value when a sinusoidal input of frequency \(f_c\) is incident on the detector. The risetime is defined as the time required for the output to increase for 10–90% of its final value as a result of an instantaneous increase in the radiant power reaching the detector.

Linearity is a statement of whether the electrical signal produced by the detector, \(S(\lambda)\), is directly proportional to the incident radiant power, \(R(\lambda)\), Equation (1)

\[
S(\lambda) = Q(\lambda) R(\lambda)
\]

(1)

The sensitivity, \(Q(\lambda)\), is defined as the slope of a plot of the electrical output of the detector versus incident radiant power, \(R(\lambda)\). For photon detectors, and for many thermal detectors, both \(Q(\lambda)\) and \(R(\lambda)\) are wavelength dependent. The sensitivity of a given detector is thus specified at a particular wavelength. Usually, radiation detectors exhibit linearity over a limited range of incident radiant power. The total range, expressed in powers of 10, for which the electrical signal is linear is called the linear dynamic range. The dynamic range is defined as the total range of incident radiant power over which the detector is responsive.
Many real detectors exhibit a small, constant response even in the absence of radiation. The small electrical output is known as the dark current. Photoemissive detectors (a type of photon detector) exhibit dark currents due to thermal emission of electrons from a photosensitive material. Dark currents in photoconductive detectors (a second kind of photon detector) occur from the elevation of electrons from the valence band to the conduction band through thermal processes. In such cases, the electrical signal contains a contribution from the dark current, $S_{\text{dark}}$. Equation (2)

$$S(\lambda) = Q(\lambda) R(\lambda) + S_{\text{dark}}$$

Dark currents can in principle be subtracted from the total electrical signal, $S(\lambda)$. Dark current measurements are made with the entrance optics of the spectrometer closed. Over short measurement periods, $S_{\text{dark}}$ is usually constant. Many of the commercial spectrophotometers vary from a lower limit of $10^{-3}$ to an upper limit of about $10^{-8}$. Dark current measurements are typically created as a result of the random thermal agitation of charged particles. The charge inhomogeneities lead to voltage fluctuations which appear in the readout as unwanted noise. The magnitude of thermal noise is given by

$$v_{\text{rms}} = (4kT R f)^{0.5}$$

where $v_{\text{rms}}$ is the root-mean-square noise voltage in frequency bandwidth $\Delta f$. In Equation (3) $k$ is the Boltzmann constant, $T$ denotes the absolute Kelvin temperature, and $R$ is the resistance in ohms of the resistive element. Examination of Equation (3) reveals that thermal noise can be reduced significantly by lowering the temperature of the component(s) and by lowering the circuit resistance. In practice, detector noise is often reduced by cooling. For example, lowering the temperature of a UV-visible photodiode array (PDA) from ambient room temperature to 77 K with liquid nitrogen would lead to a 50% reduction in the thermal noise.

Shot noise is encountered whenever electrons or other charged particles cross a junction. In radiation detectors such junctions are found at the pn interfaces of semiconductors, and in the evacuated space between the anode and cathode of vacuum tubes and photocells. The currents are composed of a series of quantized events, that is, the transfer of individual electrons across the junction. Under these conditions, the Poisson probability distribution applies and the statistical fluctuations in the average direct current, $I$, are given by

$$i_{\text{rms}} = (2I e \Delta f)^{0.5}$$

where $i_{\text{rms}}$ is the root-mean-square current fluctuation. In Equation (4) $e$ is the charge on the electron and $\Delta f$ is the bandwidth of the frequency being considered. The sources of noise, as well as their mathematical treatment, are discussed in greater detail elsewhere.

The S/N is mathematically defined as

$$S/N = \frac{\text{Signal}}{N_{\text{rms}}}$$

the ratio of the analytical signal, $S$, and the root-mean-square noise in the analytical signal, $N_{\text{rms}}$. In many spectrophotometric measurements, the overall noise level remains fairly constant and is independent of the measured electrical signal. Noise contributions thus become increasingly more important as the detector
signal decreases. The S/N provides a more meaningful measure of instrument performance than does the noise level alone. A S/N of 1000 corresponds to a relatively high precision measurement.

Multichannel charge-coupled devices (CCDs) and PDA detectors can improve the S/N for spectrophotometric measurements in two ways. First, an array detector benefits from the Fellgett advantage. The array detector monitors several wavelength regions simultaneously. The entire analysis time is spent accumulating experimental absorption/luminescence data at all wavelengths. Conventional scanning spectrophotometers, on the other hand, spend only a small fraction of the total analysis time at any one wavelength. The total analysis time is generally divided into equal time intervals. Only one time interval is spent at any given wavelength. Simultaneous wavelength detection increases the S/N by a factor of $N^{0.5}$, where $N$ is the number of spectral regions viewed (or alternatively the number of time intervals used) during the analysis time, which is held fixed. Secondly, CCD array detectors lead to an increased S/N because the individual pixels frequently outperform PMTs. Moreover, both photodiodes and CCD spectrophotometers have fewer movable parts, which greatly improves both wavelength accuracy and precision.\(^{(2)}\)

Two additional quantities have been defined to describe the noise characteristics of absorption and luminescence detectors. The noise equivalent power, $\Phi_{\text{noise}}$, is the root-mean-square power in watts that would be needed by a sinusoidally modulated input signal to cause an electrical signal equal to the root-sinusoidally modulated input incident on the radiation mean-square dark noise, $\sigma_{\text{dark}}$, in a 1-Hz bandwidth, i.e. $\sigma_{\text{dark}} = \Phi_{\text{noise}}(\lambda/R(\lambda))$. As indicated by the mathematical relationship, $\Phi_{\text{noise}}$ is wavelength dependent. A meaningful statement of the noise equivalent power requires that the wavelength of measurement be specified. The modulation frequency, detector area and electrical bandwidth should also be stated. Associated with noise equivalent power is the detectivity, $D$, which is defined as the reciprocal of $\Phi_{\text{noise}}$. The detectivity (expressed in 1/watts) is a measure of minimum detectability.\(^{(1)}\)

## 2 PHOTOCATHODE AND PHOTOSENSITIVE MATERIALS

All photon detectors use a photosensitive material to absorb the incoming incident radiation. For photoemissive photon detectors the absorbed energy leads to the emission of electrons and the subsequent development of a photocurrent that is proportional to the amount of absorbed radiation (see Equation 1). In the case of photoconductive photon detectors the absorbed radiation promotes electrons into conduction bands, with detection now based upon the resulting enhanced conductivity.

The photocathode is an important component of a photoemissive detector. Currently, two types of photocathode are used in commercial detectors. The opaque photocathode consists of a thick photoemissive material which emits electrons from the side struck by the incoming incident radiation. The transparent photocathode has the photoemissive material deposited on planar or spherical-section windows such that electrons are emitted from the backside of the photocathode opposite the incoming radiation. The spectral response of the photocathode is governed by the photoemissive material, and also by the window material in the case of the transparent photocathode. The short-wavelength limit of the transparent photocathode is determined to a large extent by the window material. Window inserts of fused silica or quartz extend the range into the far UV.

The photoemissive process responsible for converting the radiant energy into an electrical signal involves three steps. First, the photon is absorbed by the photosensitive material of the photocathode and energy is transferred from the photon to the electron. The transferred energy causes the electron to move toward the material–vacuum interface. If the electron has sufficient energy it escapes over the potential barrier at the surface into the vacuum of the tube. The energy required to release the electron from the surface corresponds to the photocathode work function, $E_{\text{cathode}}$. The energy can be used to calculate the threshold wavelength, $\lambda_{\text{thresh}}$, through the relationship $\lambda_{\text{thresh}}$ (in nm) = $hc/E_{\text{cathode}} = 1240/E_{\text{cathode}}$, where $h$ is Planck’s constant and $c$ is the speed of light. The work function represents the energy that must be given to a Fermi level electron of the metal to raise it up to the potential energy of the metal–vacuum interface. Typical work functions for pure materials range from 2–5 eV. Semiconductor materials can have substantially lower work functions.

Figure 1 depicts the radiant sensitivity (in milliamps per watt) of several types of photoemitter as a function of wavelength. Careful examination of the various curves reveals that the most sensitive photocathode compositions are the bialkali types (117 and 115), which have nominal compositions of K/Cs/Sb. Red-sensitive materials are the multialkali types (e.g. S-20 and 112 with Cs/Na$_2$/K/Sb) or Ag/O/Cs formulations (denoted as S-1). The latter photoemitter is useable up to a wavelength of about $\lambda \approx 1000$ nm. The UV end of the spectrum can be reached by coupling virtually any type of photoemitter with an optically transparent fused silica.
window. The Ga/As photoemitters exhibit a fairly flat spectral response from $\lambda \approx 440$ nm to $\lambda \approx 880$ nm, and can be used in spectrometers to measure radiant energy in the 200–940 nm spectral region.

Photoconductive detectors operate differently than the photoemissive detectors that were just discussed. A pn-semiconductor junction (a diode) is reversed-biased leading to the formation of a depletion layer. No current flows in the absence of electromagnetic radiation. When photons interact with the detector, electrons are promoted from the valence band to the conduction band where they act as charge carriers. In the photovoltaic mode of operation, an external circuit monitors the small potential change that develops across the semiconductor as electrons are promoted into the conduction band where they act as charge carriers. In the photovoltaic mode of operation, an external circuit monitors the small potential change that develops across the semiconductor as electrons are promoted into the conduction band. The current generated by the electron–hole pairs is measured in the photoconductive mode of operation. The measured signal in both cases is proportional to the instantaneous photon flux at the pn-semiconductor junction. Figure 2 depicts the approximate spectral range of the various semiconductors used in commercial absorption and luminescence detectors. At present silicon semiconductors are used for applications in the UV and visible spectral regions. Recent technological advances in fabricating materials based upon the group 13 and group 15 nitrides may in future years lead to new semiconductor materials for the UV spectral region.

Although most semiconductor diodes operate as photoconductive detectors, a Schottky diode functions in a similar fashion to a photoemissive detector. Schottky diodes are fabricated on silicon substrates with deposition of either iridium or platinum. The absorbed radiation causes electrons to be emitted from a metal layer having a low work function, rather than creating electron–hole pairs that would be expected in a semiconductor-type material. The emitted electrons are collected in the potential wells of neighboring associated structures.

### 3 PHOTOVOLTAIC OR BARRIER-LAYER CELLS

The photovoltaic cell (also called a barrier-layer cell) is a very simple absorption and luminescence detector for measuring radiation in the visible spectral region. The device consists of a flat iron or copper electrode upon which has been deposited a very thin layer of semiconducting material (e.g. selenium). A very thin transparent metallic film of silver or gold is sputtered over the semiconducting material. The metallic film acts as the collector electrode and the entire assembly is protected by a transparent lacquer coating. A typical photovoltaic cell is depicted in Figure 3.

A photovoltaic cell operates as follows. Electrons at the selenium–silver surface are excited whenever radiation of sufficient energy falls upon the semiconductor surface. Electron excitation leads to the formation of conduction electron–hole pairs. The electrons then migrate toward the deposited metallic silver (or gold) film, while the holes travel toward the iron (or copper) electrode. The liberated electrons subsequently pass through the external circuit
to interact with the holes. An electrical current develops from the electron–hole movement. Photovoltaic cells typically generate currents on the order of 10–100 mA, which are large enough to be measured with a microammeter. The measured photocurrent is directly proportional to the number of photons that strike the semiconductor surface, provided that the resistance of the external microammeter circuit is sufficiently small ( <400 Ω).

A photovoltaic cell (with selenium semiconductor) is primarily used in filter photometers to monitor radiation in the visible spectral region. The greatest sensitivity of the cell is for the green through yellow wavelengths. The current output of the cell is not easily amplified and this restricts the use of the cell to those applications where fairly high levels of illumination exist. High illumination levels eliminate the need to amplify the electrical signal.

The photovoltaic cell does provide an economical, low-cost means for measuring radiant power in the visible spectral region, particularly at high levels of illumination. The cell does suffer from lack of sensitivity at low levels of illumination and amplification of the electrical signal is not easily accomplished. Photovoltaic cells also experience fatigue with prolonged use. The photocurrent output decreases gradually during continued operation. Improved circuit design has helped to minimize fatigue effects.

4 VACUUM PHOTOTUBES

The vacuum phototube is an inexpensive photoemissive detector consisting of a semicylindrical cathode and a wire anode sealed inside an evacuated transparent tube. The concave surface of the cathode supports a photoemissive material (see Figure 1), which absorbs the incoming incident radiation. An electron may be released from the photoemissive material if the absorbed energy exceeds the photocathode work function. The emitted electron is directed towards the wire anode by the potential that is applied across the two electrodes. A current is generated by the resulting electron flow.

It should be noted that only a fraction of the photons striking the photoemissive material actually yield photoelectrons having sufficient kinetic energy to leave the photocathode surface. This is true even if the incoming photons have energies greater than the photocathode work function. The ratio of the number of photoelectrons ejected to the number of incident photons is referred to as the quantum efficiency, $Q_{\text{eff}}(\lambda)$. The quantum efficiency is wavelength dependent and typical values for most photoemissive materials range between $Q_{\text{eff}}(\lambda) = 0$ and $Q_{\text{eff}}(\lambda) = 0.50$. The rate at which photoelectrons are emitted from the photocathode, $r_{\text{cathode}}$ (in s$^{-1}$), is found by multiplying the quantum efficiency by the photon flux of the incident radiation, $R_{\text{flux}}(\lambda)$, Equation (6)

$$r_{\text{cathode}} = Q_{\text{eff}}(\lambda) R_{\text{flux}}(\lambda)$$  \hspace{1cm} (6)

Similarly, not all of the photoelectrons emitted are collected at the anode. The fraction that is collected is called the collection efficiency, $CE_{\text{anode}}$. The arrival rate of photoelectrons at the anode, $r_{\text{anode}}$, and the resulting anodic photocurrent, $i_{\text{anode}}$, are given by Equations (7) and (8), respectively

$$r_{\text{anode}} = CE_{\text{anode}} r_{\text{cathode}} = CE_{\text{anode}} Q_{\text{eff}}(\lambda) R_{\text{flux}}(\lambda)$$  \hspace{1cm} (7)

and

$$i_{\text{anode}} = CE_{\text{anode}} r_{\text{cathode}} e = CE_{\text{anode}} Q_{\text{eff}}(\lambda) R_{\text{flux}}(\lambda) e$$  \hspace{1cm} (8)

where $e$ is the electron charge, $e = 1.6 \times 10^{-19}$ C. Both expressions contain wavelength-dependent quantities. If $Q_{\text{eff}}(\lambda)$ and $R_{\text{flux}}(\lambda)$ are not constant over the wavelength range incident upon the photocathode, then Equations (7) and (8) become integrals over the wavelength range. For most vacuum phototubes the anode current must be maintained lower than $10^{-5} – 10^{-4}$ A in order to obtain a linear response.

Finally, vacuum phototubes do experience a small anodic dark current that typically ranges between $10^{-14}$ and $10^{-12}$ A. The dark current primarily results from thermal emission of electrons at the photocathode, which can occur at moderate bias voltages. Natural radioactivity from $^{40}$K in the glass housing, ionization of residual gas, ohmic leakage, and field emission are additional sources of dark current in certain instances.
The theoretical treatment of vacuum phototubes is described in greater detail in a monograph devoted to spectrochemical analysis.\(^1\)

From an operational standpoint vacuum phototubes are rarely used as fast detectors, except in those special instances that require the monitoring of low-repetition high-intensity sources. A nonexistent multiplier gain, combined with an average anode current slaved to the low cathode value, make accurate quantification of fast optical signals difficult.

5 PHOTOMULTIPLIER TUBES AND MICROCHANNEL PLATE PHOTOmultiplier TUBES

The PMT is perhaps the most widely used of the different absorption and luminescence detectors. Not too many years ago PMTs were in almost every commercial UV-visible scanning and atomic absorption spectrophotometer, phosphorescence and flame emission spectrometer, and spectrophluorometer sold. Like the vacuum phototube, the PMT is a photoemissive detector which converts radiant energy directly into an electrical signal. Electrons are emitted from the photoemissive cathode surface when it is exposed to radiation. The tube contains additional electrodes (see Figure 4) called dynodes. The first dynode is maintained at a potential of 90 V or so more positive than the cathode. Electrons emitted from the photocathode are captured by the electrical potential and accelerated toward the first dynode (second electrode). Upon striking the dynode, each photoelectron causes emission of several additional electrons from the CuBe (or MgO, GaP, CsSb) alloy coating of the secondary electrode. These electrons in turn are accelerated toward the second dynode, which is at a 90 V potential more positive than the first dynode. Again, several electrons are emitted for each electron that strikes the dynode surface. The process is repeated at each of the \( n \) dynodes in the PMT. By the time that the electrons reach the anode, the original signal will have been multiplied by a factor of \( 10^3 \) (or more). Each incident photon ultimately results in \( 10^3 \) (or more) electrons being collected at the anode. Typical gains associated with PMTs used in commercial spectrophotometers vary from a lower limit of about \( G \approx 10^5 \) to an upper value of approximately \( G \approx 10^8 \).

In using PMTs, either the average current that is produced as a direct result of the arrival of the avalanched electrons or the number of anodic pulses per unit time can be measured. The latter measurement is referred to as photon counting even though charge packets, and not photons, are actually counted. The associated electron circuits in the photon counting mode measure the arrival rate of electrons at the anode, which is given by the mathematical expression in Equation (9)

\[
r_{\text{anode}} = C E_{\text{fir dyn}} Q_{\text{eff}} R_{\text{flux}} G
\]

\[
r_{\text{anode}} = C E_{\text{fir dyn}} G \int_0^\infty Q_{\text{eff}}(\lambda) R_{\text{flux}}(\lambda) \, d\lambda
\]

where \( C E_{\text{fir dyn}} \) is the fraction of the photoelectrons from the photocathode collected by the first dynode giving rise to the secondary electron emission. The PMT gain is denoted by \( G \), \( Q_{\text{eff}}(\lambda) \) refers to the quantum efficiency of the cathode’s photoemissive surface, and \( R_{\text{flux}}(\lambda) \) is the radiation flux incident upon the photocathode. For monochromatic (or nearly monochromatic) radiation, Equation (9) reduces to Equation (7) for the vacuum phototube, except for the fact that each anodic pulse now contains \( G \) electrons. The anodic pulse of a vacuum phototube contains only a single electron as the gain is unity (i.e. \( G = 1 \)).
Figure 4 shows the structure of both the side window circular cage-type and linear focused head-on-type PMT. Both types of PMT are used in absorbance and luminescence measurements. A lower cost tends to make the side window tubes the detector of choice for routine absorbance and for steady state fluorescence measurements. For lifetime measurements there is no clearcut choice. Side window PMTs have a much faster instrumental response than commercially available linear focused PMTs. Kinoshita and Kushida\(^7\) obtained an instrument response of 160 ps full width at half-maximum (fwhm) to a 10 ps mode-locked laser excitation. Bebelaar\(^8\) reported an instrument response of 235 ps fwhm with a linear focused PMT. This is one of the faster instrument responses measured on a linear focused PMT. At this width it should be possible to determine fluorescence lifetimes experimentally down to \(\tau_{\text{fluor}} \approx 30\) ps. Side window PMTs, with their much faster response times, are able to measure smaller fluorescence lifetimes. It should be noted that in order to obtain the faster pulses, it is necessary to irradiate only a very small area of the side window PMT’s photocathode. This requirement does restrict the sensitivity of the measurements to a level which can only be tolerated when using mode-locked laser excitation.

If instrument response time were the only consideration, then a side window PMT might be the detector of choice for time-resolved fluorescence measurements. One of the advantages afforded by linear focused PMTs is a slower transit time dependence on the point of photocathode illumination. Commercial linear focused PMTs have a transit time dispersion of about 13 ps mm\(^{-1}\).\(^9\) With a linear focused PMT there is no need to sacrifice sensitivity by reducing the illuminated area in order to obtain the maximum time resolution. The spectral ranges of side window and linear focused PMTs are comparable.

Determination of fluorescence lifetimes requires a minimum fast time response of 1.5 ns (or less) risetime. In PMTs the risetime originates from the distribution in anode arrival times of the avalanching electrons produced by simultaneously triggered photocathode events. A distribution in arrival times results because the ejected electrons have different energies and the electrons take slightly different pathways in traveling to the next anode. A single electron emitted at the photocathode will yield a several nanosecond distributed current pulse by the time the event is finally detected at the anode.

Manufacturers have been successful in reducing the risetime by replacing the early unfocused box-and-grid and venetian blind photocathode–anode configurations by the circular cage and in-line designs shown in Figure 4. Planar cathodes, which can have edge-to-center transit time differences as large as 10 ns, have been replaced by curved photosensitive surfaces. The two aforementioned modifications have helped to reduce the risetime of the PMT to 1–2 ns. The risetime can be further reduced by utilizing dynode materials such as GaP which emit more secondary electrons when impacted by a high-energy electron. The new GaP coatings can emit as many as 50 electrons per each electron impact, i.e. \(\Gamma = 50\). This allows the total number of dynodes to be reduced, while still maintaining the high gains necessary to detect low levels of incident radiation. Several commercial PMTs employ a GaP coating for only the first dynode. For such PMTs, the gain achieved by the detector is given by \(G = \Gamma_{\text{GaP}} (\Gamma_{\text{other}})^{n-1}\), where \(n-1\) represents the number of non-GaP dynodes in the PMT.

In addition, modern PMTs impose high electric field strengths at the dynode surfaces and use crossed electric and magnetic field strengths to control the pathway the electrons take to reach the next dynode better. The above modifications have enabled construction of PMTs having \(\approx 150\) ps risetimes. From an operational point of view, the detector should have a risetime that is short compared to the variation in the signal being measured. As a rule-of-thumb, the risetime should be one-tenth (or less) of the variation in the measured signal.\(^3\)

Fast instrument responses and fast risetimes are important considerations in detector selection for time-resolved studies. In certain instances involving single photon events it might be possible to reference measurements to some fixed point on the resultant output pulse. A fast risetime is no longer as important if a reference point is used. Detector selection then becomes governed more by the time jitter of the anodic pulse maximum for repeated equivalent events. The variation in transit time follows roughly a Gaussian distribution, with the width being one-quarter to one-third that of a delta-function response pulse. Anode jitter time can be extremely sensitive to the extent of optical coverage afforded by the photocathode.\(^3\)

Dark currents in PMTs result from the thermal emission of electrons at the photocathode surface, ionization of residual gas, natural radioactivity from \(^{40}\)K in the glass, ohmic leakage and thermal emission of electrons from the dynodes. The first four sources were identified previously as causes of dark current in vacuum phototubes. Dark currents in PMTs typically are in the range of \(10^{-11}–10^{-7}\) A. Thermal emission of electrons from the photocathode (or early dynodes) are multiplied by the full gains of the PMT. The amplification leads to the much larger dark current of the PMT, compared with the \(10^{-14}–10^{-12}\) A dark current for vacuum phototubes.

In early analytical applications PMTs were used to monitor radiation in both the UV and visible spectral regions. The majority of photoemissive materials listed in Figure 1 have their maximum sensitivity somewhere in the 200–600 nm wavelength region. In the vacuum UV, from about \(\lambda \approx 30\) nm to \(\lambda \approx 190\) nm, the sensitivities of the photoemissive materials in Figure 1 are generally quite
low. Radiation can be successfully detected, however, by adding a fluorescing plate (sodium salicylate on a Pyrex window) as a converter in front of the PMT. Whenever radiation strikes the added window, the compound fluoresces at about 400 nm, leading to a reasonably linear PMT signal across the cited spectral range. For many years the best IR sensitive photocathode material was Ag/O/Cs, denoted as S-1 in Figure 1. The modest quantum efficiency, $Q_{\text{eff}}$, of Ag/O/Cs may explain why very few red and near-IR (600–1000 nm) fluorescence measurements were made until just recently. Most photoemissive detectors lacked sensitivity in this spectral region. Red and near-IR fluorescence measurements are now possible using PMTs equipped with an In/Ga/As (Cs) photocathode, which offers improved performance out to $\lambda = 1010$ nm and a dark current 100 times smaller than the S-1 photocathode.\(^{(10)}\)

Microchannel plate photomultiplier tubes (MCPPMTs) have been around for several years. It was not until recently, however, that the detector made an impact in fluorescence lifetime studies. Electron magnification occurs as electrons travel between thin glass plates through the many microscopic channels. Each channel is lined with a secondary emitting surface and functions as an individual electron multiplier. The glass surfaces of each plate between channels are coated with a thin nichrome (or other conducting material) layer and a large voltage ($\sim 1000$ V) is applied across the thickness of the plate to direct the flow of electrons toward the anode. Figure 5 depicts a MCPPMT with three plates.

![Figure 5](image_url)

**Figure 5** Schematic diagram of a MCPPMT detector (top), depicting the hexagonal arrangement of the plate’s microchannels. The bottom drawing shows the electron amplification which takes place in the individual microchannels when electrons strike the secondary emitting surface.

The MCPPMT operates in the following fashion. A photoelectron emitted from the photoemissive surface of the photocathode when exposed to incident radiation is accelerated a short distance (approximately 3 mm) to the first microchannel plate (MCP). The photoelectron enters one of the channels of the plate where it eventually strikes the wall producing secondary electrons. These electrons in turn are accelerated further down the channel and additional collisions occur. On the average between one and three secondary electrons are released per collision. Upon exiting the channel, the electrons spread out and enter a number of adjacent channels in the second MCP (see Figure 5). Further multiplication occurs in the second and in each succeeding MCP. Spatial information is maintained since the secondary electrons are confined within the microchannels. After the electron cascade passes through the last plate it is finally collected at the anode as a pulse of current.

MCPPMTs are more compact than conventional PMTs, and as a result electrons travel much shorter distances. The more compact design leads to both faster time responses and less fluctuation in the length of time between the release of the first photoemissive photoelectron and its subsequent detection as an anodic current pulse. Risetimes of 150 ps and a transit-time jitter (i.e. impulse response) of approximately 25 ps fwhm at 200 counts s$^{-1}$ noise at ambient room temperature have been recorded with a commercial 6-µm channel MCPPMT.\(^{(11)}\) The compact design of the MCPPMT makes it amenable to cooling. Each MCP can provide, depending upon length and secondary emitting surface, electrons gains of $10^3–10^4$ over an active diameter of more than 30 mm with an electron equivalent input noise of $10^{-16}–10^{-15}$ A cm$^{-2}$. When placed in tandem, as would be the case with a MCPPMT, combined MCP can give gains of $G = 10^8$ to $G = 10^9$, which are comparable to those obtained with conventional PMTs.\(^{(12)}\)

### 6 PHOTODIODE AND PHOTODIODE ARRAY DETECTORS

Photodiode absorbance detectors operate differently from the vacuum phototubes and PMTs that were just discussed. In a photodiode the incoming radiation promotes electrons from the valence band to the conduction band of a semiconducting material, as opposed to releasing electrons from a photoemissive surface. A semiconductor is a crystalline material having a conductivity between that of an insulator and a conductor. Crystalline silicon and germanium are the two semiconducting materials that have found widest application in the construction of electronic devices. Both elements are in group 14 of the periodic table and thus have four valence electrons for
bond formation. All four valence electrons are localized in the silicon/germanium crystal through covalent bonding with neighboring atoms. In theory, silicon and germanium should behave as insulators since there are no free electrons in the crystalline lattice. Sufficient thermal agitation occurs at ambient room temperature, however, to liberate an occasional covalently bonded electron. The liberated electron is free to move about the crystalline lattice to conduct electricity. Thermal excitation also leaves a positively charged region where the liberated electron once resided. The positively charged region, referred to as a hole, is also mobile in that a bound electron from a neighboring Si (or Ge) atom jumps to the electron deficient region and in turn leaves behind a hole. Conduction in a semiconductor involves movement of thermal electrons in one direction and holes in the other direction. The conductivity of a Si (or Ge) crystal can be enhanced by judiciously adding a small controlled amount of group 13 or group 15 impurity. Replacement of a silicon atom with a group 15 element (As or Sb) introduces one unbound valence electron into the structure (see Figure 6). Very little thermal energy is needed to free this extra electron for conduction of electricity. A Si (or Ge) crystal that has been doped with a group 15 element is referred to as an n-type semiconductor. Electrons are the majority charge carriers. Holes still exist as the result of thermal agitation of silicon atoms; however, their number is small compared to the number of electrons. Similarly, a p-type semiconductor is formed whenever a Si (or Ge) crystal is doped with a trivalent group 13 (In or Ga) element. An electron deficiency exists at each place where In (or Ga) is inserted. Holes are created in the crystalline lattice whenever covalently bonded electrons from neighboring Si (or Ge) atoms move to the vacant orbital associated with the group 13 impurity atom. Movement of holes from one Si (or Ge) atom to another, as described above, leads to a current in which the majority carrier is positive. A p-type semiconductor is inherently less conductive than a n-type semiconductor. Holes are less mobile than free electrons.

A photodiode is formed by having adjacent p-type and n-type regions within a single silicon or germanium crystal. Close proximity of n-type and p-type materials permits movement of holes from the p-region into the n-region and movement of electrons in the opposite direction. When the diode is reversed-biased (see Figure 7) the majority carriers in each region drift away from the junction to form a depletion layer, which contains few charges. Essentially no current flows in the absence of electromagnetic radiation. When photons strike the semiconductor, electrons are promoted from the valence band to the conduction band where they act as charge carriers. The current that is produced is proportional to the incident light intensity.

Photodiodes are used as absorbance detectors to monitor radiation in the UV-visible and near-IR spectral regions. The spectral response of most photodiodes

![n-Doped silicon crystal](image)

reaches a maximum in the near-IR spectral region ($\lambda = 800–1000\text{ nm}$). These devices exhibit excellent linearity over six to seven decades of incident radiation power. Photodiodes have subnanosecond response times. Design simplicity and small size, combined with the performance characteristics listed above, have made photodiodes a very popular detector for analytical applications where light levels are relatively high.

MCPs have been used in several instances to intensify signals prior to detection by a photodiode detector. These devices operate in similar fashion to the MCPPMTs, except that the electrons upon exiting the MCP are now accelerated towards a phosphor screen. The resulting photons are coupled with a fiber-optic bundle to the photodiode. The photodiode monitors the photon bursts at the phosphor screen. MCPs are designed to provide a $10^3–10^4$ gain prior to detection by a silicon photodiode. Bormett and Asher\textsuperscript{(13)} reported that diffraction can pose problems when using MCP intensifiers. Diffraction redirects a fraction of the spectrophotometer-dispersed radiation back into the instrument, where it may be reflected or scattered from other optical components and later reimagined onto the detector.

Avalanche photodiodes (APDs) are used in analytical applications, such as single-photon timing and phase fluorometry,\textsuperscript{(14–24)} which require both a fast response and high sensitivity. These devices are operated in the reversed-biased breakdown region of the pn junction and provide an internal gain of up to $G = 1000$. The electron–hole pairs produced by the impinging incident radiation create additional pairs in an avalanche effect. Careful control of the bias voltage is required in order to obtain the stable current gains needed for accurate measurements. Response times do depend upon the internal gain. Very fast instrumental response widths as low as 70 ps fwhm have been reported for single-photon timing experiments.

Silicon single-photon APDs provide excellent responsivity down to wavelengths of $\lambda = 1000\text{ nm}$. Germanium (Ge) and InGaAs photodiodes are used to monitor longer wavelengths (see Figure 2). These semiconductors have relatively high quantum yields; however, they do give fairly noisy signals at ambient room temperature. This is particularly true in the case of Ge semiconductors. PDA detectors used for near-IR studies are often cooled to below room temperature in order to reduce the noise. The noise problem is further addressed by minimizing the photodiode active area as much as possible. Noise is proportional to the active surface area. Areas of less than 1 mm$^2$ are required to achieve subpicowatt noise levels. In the case of single photon APDs, the surface areas are typically in the neighborhood of 10 μm in diameter. The small active surface area significantly reduces the detector’s sensitivity, to the point where a microscope and/or high-powered laser source may be needed for accurate quantification. It should also be noted that APDs can exhibit a wavelength-dependent tail in their response due to charge carriers generated in the neutral p-region beneath the depletion layer. The tail becomes more pronounced at longer wavelengths and can hinder convolution analysis of single-photon timing experiments.\textsuperscript{(14)}

Since the late 1970s rapid advances in semiconductor-based technology and the related development of powerful microprocessor systems led to the evolution of numerous multichannel absorption and luminescence detectors. Multichannel detectors enable the analyst to acquire a large amount of spectrally and/or spatially resolved data in a single observation. The linear photodiode array (LPDA) detector consists of an array of photodiodes (also called elements, channels and pixels). Each photodiode acts as a separate photon-to-charge transducer and a charge storage device. Linear arrays designed for commercial UV-visible spectrophotometers are spaced on 25-μm centers and have apertures of 2.5 mm. This particular design gives an aspect ratio of 100:1, which corresponds to the typical aspect ratio of a conventional UV-visible scanning spectrophotometer or polychromator slit. A reversed-biased pn semiconductor diode serves as each photosensitive element. Readout is performed by a shift register operating in real-time, variable integration, diode group or “skipping-diode” mode. Commercial units read out and digitize the diode information at rates from 4–28 ms per photodiode. The various readout modes are reviewed in a two part series devoted to PDA detectors in UV-visible spectroscopy.\textsuperscript{(25,26)}

Figure 8 depicts a LPDA being operated under reversed bias. The PDA consists of p-type bars diffused

![Figure 8 Diagram of the LPDA showing reversed bias pn junction with diffused p-type bars in the n-type silicon substrate. (Redrawn with permission from D.G. Jones, Anal. Chem., 57, 1057A–1073A (1985). Copyright American Chemical Society.\textsuperscript{(21)})](image-url)
into a n-type silicon substrate. Both semiconductor types are photosensitive. The capacitive diode is fully charged at the beginning of each measurement cycle. Electron–hole pairs form upon irradiation. Charges generated from light incident on the areas between diodes (i.e. between p-regions) divide proportionally between adjacent diodes. Photogenerated electron–hole pairs separate in the electric field, with the electrons and holes drifting to the positively charged cathode and negatively charged anode, respectively. A leakage current flows if the diode remains connected to the voltage source. This current is proportional to the photon flux incident on the diode. If the diode were to be disconnected from the voltage source, then the electron–hole pairs will discharge the potential previously stored. The photon flux incident upon the diode is found by measuring the current needed to recharge the diode to its original value, or by measuring the resulting change in potential across the diode.

PDAs are available commercially in both linear and area formats. Linear PDA are useful for monitoring radiation in the 200–1000-nm spectral region. Two-dimensional PDAs have found application in analytical chemistry for measuring radiation in the near- and mid-IR regions. Long-wavelength materials, such as HgCdTe, InSb and InGaAs (see Figure 2) allow measurements to be made down to a wavelength of \( \lambda = 1800 \text{ nm} \) (or longer). Two-dimensional PDAs can either be used for direct wavelength detection on the focal plane of a spectrograph, or used in conjunction with a modulated radiation source to generate chemical specific maps of a sample.\(^{2}\)

Parameters that govern the overall performance of PDA spectrophotometers include dynamic range and precision, spectral resolution, S/N, level of stray radiation and sensitivity. These parameters are determined to a large extent by the photodiode size and spacing. As a general rule-of-thumb, the dynamic range increases with increasing diode size, whereas greater resolution is obtained with the narrower photodiodes. The photodiode dimensions that match the spectrophotometer slit offer the best compromise for maximum resolution and dynamic range. Linear PDAs inside of commercial UV-visible scanning spectrophotometers have a spectral resolution of \( \pm 1 \text{ nm} \) in the UV spectral region (200–400 nm) and \( \pm 2 \text{ nm} \) in the visible range (400–800 nm). PDA detectors designed for spectroscopic applications have a dynamic range of about \( 10^4 \) for single integration time,\(^{27}\) which is over two orders of magnitude smaller than can be obtained with a PMT. The linear dynamic range of a LPDA is in general lower than that of a single photodiode. (A single photodiode exhibits linearity lower than six to seven decades of incident radiation power.) The lower dynamic range results from internally reflected light from the window, the silicon wafer and spectrophotometer’s metallic parts. Finally, PDAs do benefit from the Fellgett advantage in that the entire analysis time is spent making measurements at all wavelengths. The largest signal is obtained whenever the time between readouts is increased until the signal is just below saturation (i.e. integrate the signal on-chip). On-chip integration increases the S/N proportionally to the exposure time, as opposed to the square root of the accumulated exposure time in the case of conventional ensemble average.\(^{25}\)

The quantum efficiency, \( Q_{\text{eff}} \), of a PDA is quite high, however, the recharge process is quite noisy and may result in a readout noise of greater than 1000 electrons. A large readout noise significantly degrades S/Ns for weak signals. In analytical chemistry PDAs are generally used in applications, such as absorption spectroscopy, where illumination levels are high. PDA detectors (without intensifiers) are virtually useless in Raman spectroscopy because the readout noise overwhelms the weak scattering signal. Also, the dark current signal can be fairly large due to capacitor leakage, which would preclude S/N improvements based upon longer integration times. To apply the PDA to Raman spectroscopy successfully, the signal must be amplified significantly above both the readout and dark noise. MCPs have been used to boost weak Raman scattering signals for subsequent PDA detection, with only slight degradation of spatial resolution being observed. The MCP is placed prior to the PDA. Electrons exiting the MCP hit a phosphor screen and the PDA monitors the resulting photon bursts. MCP intensified PDAs have a major advantage when time resolution is required. The MCP can be switched on and off quickly. Although the PDA is integrating the signal during the entire time between readouts, the intensifier gain is so large that only the photons arriving when the MCP is on are counted. The “contrast ratio” between gate on and gate off signals is typically \( 10^6 \) (or larger).

Linear PDAs have completely revolutionized absorbance detection in high-performance liquid chromatographic (HPLC) separations. Analysts now obtain multiwavelength chromatograms from a single injection, which decreases the analysis time and facilitates both solute identification and quantification. In cases where the solutes are not resolved by the column but where spectral overlap is minimal, it is possible to determine the concentration of all components within a single elution profile by judiciously monitoring each component at wavelength(s) that are free of interference. One can select between the wavelength of maximum absorbance to achieve greater sensitivity, or the wavelength giving the optimum signal relative to possible interferences if greater selectivity is desired. Prior to LPDAs, several injections would be needed to obtain the same information. The output intensity from several discrete photodiodes can be summed to increase the detectability by a factor of

\[ Q_{\text{eff}} \]
five-fold to 500-fold. Moreover, simultaneous data acquisition at different wavelengths also ensures the detection of most mixture components. The applicability of LPDA:s in HPLC is described in several review articles.\textsuperscript{26,28,29}

7 CHARGE TRANSFER DEVICES

PDAs do not offer the sensitivity, dynamic range, linearity and noise performance to be competitive with PMTs in many analytical applications. PDAs are used primarily in those applications where a broad spectral region needs to be monitored simultaneously (e.g. kinetic studies, HPLC detection). Here, the multichannel advantage outweighs the noise, cross talk and limited sensitivity and dynamic range shortcomings of PDAs. Recent advances in solid state and semiconductor technology have led to new multichannel detectors incorporating charge transfer devices (CTDs), which have performance characteristics comparable to commercial PMTs. Hanley et al.\textsuperscript{30} derived mathematical formulas describing CTD performance with regard to minimum and maximum detectable absorbance, maximum S/N and maximum dynamic range for absorbance and luminescence measurements.

CTD is a generic term given to two types of related solid state radiation detectors, the CCD and the charge injection device (CID). The CCD was co-invented by Willard Boyle and George Smith in 1969. These two individuals, who were employees of Bell Laboratories, wanted to develop a silicon diode for a picturephone. They devised a method for passing charge from one capacitor to another by changing an applied voltage in a coordinated fashion. This idea led to the CCD, which was subsequently constructed and tested at Bell Laboratories.

Three years later Gerry Michon and Hugh Burke, employees at General Electric Company’s corporate research center, built the first CID by placing two adjacent metal-oxide semiconductor (MOS) capacitors on the edge of a wafer of an experimental device. This construction was found to be light sensitive. The historical development of both CCDs and CIDs is reviewed in greater detail elsewhere.\textsuperscript{31}

The MOS capacitor is an important component of CTDs. A MOS capacitor consists of a gate electrode overlying insulating, epitaxy and substrate layers. The substrate is crystalline silicon (~0.5 mm thick for mechanical support) which has been highly doped with either a group 13 (p-type, CCDs) or a group 15 (n-type, CID:s) element for electrical conductivity. The gate electrodes are made of a semitransparent, highly polycrystalline silicon material. The epitaxy is a thin lightly doped region that forms the photoactive region of the MOS capacitor. The epitaxy is p-doped for CCDs and n-doped for CIDs. Insulating silicon oxide and nitride layers separate the epitaxy from the gate electrode structures. The gate and epitaxy form the two capacitor plates.

CTDs operate much like a photographic film in that they integrate signal information when irradiated. The basic operation of a CTD detector can be illustrated using Figure 9, which depicts the cross-section of a single pixel of a CTD in the charge integration mode. In this case, the pixel consists of two conductive electrodes that overlie an insulating layer of silicon oxide. The silicon oxide layer separates the electrodes from a region of n-doped silicon. Electrons are the majority charge carrier for this example. When the two electrodes are negatively charged with respect to the silicon, a charge inversion layer is created under each electrode. The mobile holes created by the absorption of photons migrate and collect under the electrodes. This region, called a potential well, is capable of holding up to $10^5$–$10^6$ charges before overflow to an adjacent pixel (referred to as blooming). As shown in Figure 9 the right electrode is maintained at the more negative potential. Positive charge thus accumulates under the right electrode. The amount of charge in a CTD detector during exposure to radiation can be measured in one of two ways. First, in a CCD the charge is moved to a charge-sensing amplifier for measurement. Alternatively, the voltage change that results from movement of the charge from the region under the right electrode to the region under the left electrode can be measured. The latter measuring mode is used in CIDs.

Figure 10 shows how cycling of gate potential sequentially shifts a charge packet from gate to gate to move it across the CCD. Note a CCD collects photogenerated electrons, rather than holes, under the electrodes as the

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure9.png}

Denton, \textit{Anal. Chem.}, 60, 282A–291A (1988). Copyright American Chemical Society.\textsuperscript{32})}
\end{figure}
silicon substrate is doped with a p-type impurity. The device depicted in Figure 10 has three-gate pixels and a three-phase architecture, i.e. three transfers are required to move the charge across a single pixel. First, the charges in the vertical registers (referred to as the parallel shift register) are shifted downwards one register. The charges that were shifted into the horizontal register (also called the serial shift register) are then transferred sequentially into a summing well and then to a readout amplifier. Once the serial register is emptied, the entire process begins again with another vertical shift, and continues until all of the pixels are emptied.

Charge blooming is the leakage of accumulated charge from an illuminated detector element to adjacent elements. The onset of blooming in a CCD occurs whenever the maximum number of photogenerated charge carriers that can be held in an element is exceeded. Channel stops in the parallel shift register prevent charge blooming across columns and as a result the bloomed charge spills down the column. Manufacturers now offer CCDs with antiblooming drains, which accumulate and transport away the excess photogenerated charges. These CCDs generally exhibit slightly lower quantum efficiencies. Part of the area is taken up by the antiblooming drain.

CCDs are currently being used in UV-visible absorption, fluorescence and Raman spectroscopies, where measurements might require the long integration of low intensity radiation. Epperson et al.\textsuperscript{(33)} reported a detection limit of anthracene of 1 ppt at S/N = 2 based upon fluorescence measurements with a relatively weak 35-W deuterium lamp excitation source. The reported detection is an order of magnitude lower than that determined using a high-powered tunable dye laser excitation source.\textsuperscript{(34)} Murray and Dierker\textsuperscript{(35)} studied monolayers of organic sorbates of different substrates by unenhanced Raman spectroscopy. The authors reported a S/N = 15 when measuring the monolayer coverage of cadmium stearate films deposited on glass and silicon surfaces with a CCD. Zhao and McCreery\textsuperscript{(36)} successfully demonstrated the applicability of a CCD as a radiation for Fourier transform (FT) Raman spectroscopy in the near-IR region. Measurements revealed that the common path interferometer-CCD spectrometric system possessed many of the advantages inherent to FT
spectroscopy (e.g. high throughput, excellent frequency precision and wide spectral coverage) and CCD detection (shot-noise limited operation). The observed S/N of the multichannel FT system was comparable to that for a dispersive spectrometer for the same laser power and integration times.

Modified CCDs have been used in conjunction with an echelle grating inductively coupled plasma emission spectrometer to study samples containing up to 72 different elements. The detector, called a segmented array charge-coupled device (SCD), consisted of 224 linear CCDs imbedded into a monolithic silicon block. The light beam originating from the torch is split by a Schmidt cross-disperser. Cross-dispersed radiation is focused onto an SCD for intensity measurements in the UV spectral region (160–375 nm). The undispersed radiation is passed through a prism for cross-dispersion and subsequently focused onto a second SCD for intensity quantification in the visible (375–782 nm). Each array segment can be addressed separately and the charge integration time can be varied over a wide enough range to provide dynamic ranges of 10^5 or greater.

CIDs operate in a similar fashion, except for the method of measuring the charge accumulated under the electrode. Each pixel of a CID is defined by the intersection of a row and column gate electrodes as shown in Figure 11. At the beginning of a measurement period negative potentials are applied to both electrodes, which leads to the formation of potential wells that collect and store holes formed in the n-doped silicon substrate by absorption of photons. Holes preferentially migrate to the collection gate because of its more negative potential. Excess charge rarely spills over into adjacent elements. After integration (or the end of the measurement time), each pixel is read using correlated double sampling. The potential gate for the sense gate is disconnected and the potential read (step B in Figure 11). The holes that have accumulated under the collection gate are then transferred to the sense gate by changing the potential applied to the collection gate from negative to positive. The new potential of the sense gate is measured. The difference between the two potential readings is proportional to the charge collected in the well. The preceding examples describe only a few of the many published applications where either a CCD or CID was used. CTDs have been used as absorbance and luminescence detectors in nearly all areas of analytical chemistry including molecular luminescence.

Published articles^39–41 have also reported that two-dimensional CID array detectors can be used in an echelle spectrograph for direct current and inductively coupled plasma atomic emission spectroscopy. Dark currents in the detector elements are minimized by housing the unit in a liquid nitrogen cryostat maintained at a temperature of 135 K. Two-dimensional CID arrays possess the necessary number of resolution elements for measuring hundreds of emission lines and surrounding background. Analysis of complex samples requires that several emission lines and associated background regions be measured for each element in order to reduce errors arising from matrix effects. The preceding examples describe only a few of the many published applications where either a CCD or CID was used. CTDs have been used as absorbance and luminescence detectors in nearly all areas of analytical chemistry including molecular luminescence.
emission spectroscopy, Raman spectroscopy, X-ray diffraction, microscopy and chemical separations.

8 STREAK TUBES AND STREAK CAMERAS

The streak camera is a device that converts time information from a luminous event into spatial information. Streak cameras are capable of measuring fast optical signals. There are two general types of streak cameras, the mechanical and the image convertor. In the mechanical version the signal is swept quickly across a piece of photographic film by a high-speed rotating mirror. Typical performance characteristics would be 2–100-ns resolution and a 15–800-ms time window. In the image convertor (Figure 12) electrons emitted from the photocathode upon irradiation are extracted by the grid and accelerated at high velocity toward the anode. After passing through a hole in the anode the electrons are deflected by the voltage ramp applied to the deflection plate. The voltage ramp increases in strength with increasing time. A MCP intensifier may be used to multiply the number of electrons prior to detection. Upon exiting the MCP, the electrons strike a phosphor screen. The result of the aforementioned processes is that the time dependence of the radiation intensity is translated into the distance dependence of electron impact upon the phosphor screen. The shape of the voltage ramp used to deflect the electrons determines the relationship between time and impact distance. Photon bursts from the phosphor screen can be photographed with a normal camera, or sent to a CCD for quantification. Image convertors have time resolutions of 0.1–20 ps. The main advantage that streak cameras have enjoyed over photon counting methods has been time resolution. Streak camera time resolutions of 0.5 ps fwhm (or less) are obtainable. The best time-resolved single-photon counting methods, employing fast MCP-PMTs, are about two orders of magnitude longer in fwhm.

Many of the early streak cameras were plagued by time and intensity nonlinearity, flyback artifacts and a limited dynamic range. Manufacturers have now overcome many of these problems with improved designs. Streak cameras were designed to measure the time dependence of light emitted by a sample. Several of the processes that can be monitored include: protein binding reactions (0.1 ps to 1 ms); energy transfer in proteins (<1 ps to 100 ps); rotational diffusion (<1 ps to >1 ns); excited state proton transfer (<10 ps to >100 ps); electronic relaxation (<1 ps to 100 ns); and exciplex formation (<10 ps to 10 ns). The corresponding timescales, picoseconds (ps) to milliseconds (ms), are given in parentheses. Several of these processes can also be monitored with absorption spectroscopic methods.

9 THERMAL DETECTORS

Thermal detectors, which are used in the IR region, sense the change in temperature that results from the absorption of incoming incident radiation. Thermal detectors are made of low heat capacity materials as the radiant power level from a typical IR beam is small (in the range of 10^-9–10^-7 W). The size and thickness of the absorbing element is minimized as much as possible and every effort is made to focus the entire IR beam onto the detector surface. Thermal detectors are housed in a vacuum and carefully shielded inside the spectrometer. The beam from the radiation source is generally chopped to minimize further the undesired efforts of extraneous heat. The analytic signal would then have the frequency of the chopper and could easily be distinguished from extraneous noise, which would vary slowly with time.

The first of the thermal detectors to be considered is the thermocouple, which consists of a pair of junctions formed whenever two identical pieces of metal (e.g. Bi) are fused to each end of a dissimilar metal (e.g. Sb). One junction serves as a reference of “fixed” temperature, while the second junction becomes the sensor for IR radiation. (Note, the reference junction does not need to be maintained at constant temperature if the analytical signal is chopped.) The sensing transducer junction is normally blackened to improve its heat-absorbing capacity and sealed in an evacuated chamber.

![Figure 12 Diagram of a streak tube, which is the heart of the streak camera system. The MCP (not required) multiplies the number of electrons prior to their impact on the phosphor screen. A streak camera system would also include the camera or CCD for recording the photon bursts.](image-url)
having a window made from a material that is optically transparent to IR radiation. The reference junction is designed to possess a relatively large heat capacity and is carefully shielded from the incident radiation. A potential develops between the two junctions that varies with the difference in temperature of the junctions. A well-designed thermocouple IR detector is capable of responding to temperature differences as small as $10^{-6}$ K. The thermocouple detector has uniform spectral response in the 1–40-µm wavelength region, excellent linearity and reasonable sensitivity. The detector's sensitivity can be further enhanced by connecting several thermocouples in series. Now, the output potential is the sum of the potentials across the individual thermocouples. Multiple thermocouple devices are referred to as thermopiles. Thermocouple detectors are used in dispersive mid-IR spectrometers.

IR radiation can also be detected with thermistors. These detectors are constructed from intrinsic semiconductor materials that exhibit relatively large changes in resistance as a function of temperature. The responsive element is again kept small and blackened to absorb radiation. The thermistor is generally placed in a bridge circuit (e.g. Wheatstone bridge) with a reference thermistor that is not irradiated. The resistance can be measured by a null-comparison technique, or the out-of-balance voltage of the bridge can be monitored. Thermistors exhibit moderate sensitivity and a wide linear range.

Thermocouples and thermistors respond considerably slower than PMTs, CCDs, CID and photodiodes because time is required for the temperature of the element to change. Typical response times for thermocouples and thermistors are in the range of 0.01 to 0.1 s. Such response times are much too slow for FT spectroscopy. Commercial Fourier transform infrared (FTIR) spectrometers use pyroelectric or Golay detectors, which exhibit responses that are fast enough to track the changes in the time-domain signal from an interferometer.

Pyroelectric detectors are constructed from single crystalline wafers of pyroelectric materials, such as triglycine sulfate (usually deuterated with a fraction of the glycines replaced with alanine), lithium niobate (LiNbO₃) or lithium tantalate (LiTaO₃). Pyroelectric substances exhibit a large spontaneous electrical polarization at temperatures below their Curie point, which in the case of triglycine sulfate is 47 °C. (LiNbO₃ and LiTaO₃ have higher Curie points and do not exhibit hygroscopicity, which is sometimes a problem encountered with triglycine sulfate.) If the temperature of a pyroelectric material is changed, then the degree of polarization is changed. The change in polarization can be quantified by placing the pyroelectric crystal between two electrodes to form a capacitor. When the polarization changes, the charges induced on the electrodes create a measurable current in an external electric circuit that connects the two sides of the capacitor. The output current is proportional to the surface area of the crystal and to its rate of change of polarization with temperature. Pyroelectric detectors have fairly fast response of less than 1 ms over most of the IR region encountered in analytical chemistry. For wavelengths below 2 µm, the triglycine sulfate must be blackened to enhance photon absorption. This can slow the detector’s response. Linear arrays of pyroelectric detectors are also available.

It should also be noted that thermocouples, thermopiles and pyroelectric devices have also been utilized in conjunction with electrical substitution radiometers in absolute photon flux measurements. The detector is a thermal sensor in contact with a good absorber of radiation and an electric heater. Photons are absorbed by the thermal sensor and the detector output, $T_{\text{radiation}}$, is read. The radiation source is then shuttered to prevent light from reaching the detector. Once the sensor returns to its original temperature electric power is applied to the heater until the detector’s output reaches $T_{\text{radiation}}$. Measurement of the electric power when $T_{\text{electric}} = T_{\text{radiation}}$ yields the equivalent of the radiant power absorbed. Sensitivities of electrically calibrated pyroelectric radiometers range from 100 mW down to 100 µW full scale.

Golay detectors can be used in FTIR spectrometers having slow-scanning and/or stepped-scan interferometers. Figure 13 depicts a Golay cell, which is essentially an airtight pneumatic chamber filled with a gas of low thermal conductivity (e.g. xenon). The chamber is closed at one end by a thin rigid blackened metal plate and by a flexible silvered diaphragm at the other end. Radiation passes through a small IR-transmitting window and is absorbed by the blackened plate. Heat, conducted to the gas, causes it to expand and distort the flexible

---

**Figure 13** Schematic diagram of a Golay cell.
diaphragm. A fine leak connects the detection chamber to a ballasting reservoir of gas to prevent ambient room temperature changes from affecting the measurement. Light from a tungsten filament lamp is focused upon the silvered diaphragm and is reflected back to a PMT (or other suitable radiation detector). Distortion of the silvered diaphragm moves the light beam across the PMT surface and changes its electrical output. Golay detectors are considerably more sensitive than thermocouples. Response times are typically on the order of 20 ms. Golay detectors may be used only with slow-scanning or stepped-scan interferometers, and where the IR radiation is modulated by an external chopper. Radiation modulated in the audiofrequency regime must be detected by either pyroelectric detector or semiconductor detector (e.g. PbS, PbSe and HgCdTe).(50) As noted previously, semiconductor detectors can be operated in either the photovoltaic or photoconductive model. The approximate spectral ranges of the various semiconductors used in commercial absorption and luminescent detectors are given in Figure 2. This list will undoubtedly grow in number in future years as new semiconducting materials are produced and tested.

ABBREVIATIONS AND ACRONYMS

APD  Avalanche Photodiode
CCD  Charge-coupled Device
CID  Charge Injection Device
CTD  Charge Transfer Device
FT  Fourier Transform
FTIR  Fourier Transform Infrared
fwhm  full width at half-maximum

In fluorescence microscopy, an optical microscope creates a magnified image of the fluorescence and phosphorescence of specimens excited by light. Autofluorescence is the intrinsic fluorescence of a specimen, which is often weak. To enhance fluorescence, tags are added, such as fluorescently labeled antibodies which precisely localize specific molecular components. Living cells and tissues may be labeled with a variety of parameter-indicating fluorophores to measure ion concentrations, electrical potentials and specific chemical species. Thick living specimens create problems of superimposition and haze from out-of-focus fluorescence, but advances in confocal fluorescence microscopy and multiphoton fluorescence microscopy now permit successful fluorescence imaging of thick living specimens with submicrometer three-dimensional resolution.

1 INTRODUCTION TO OPTICAL MICROSCOPY

1.1 Lateral Resolution

Optical microscopy provides useful magnification to about 2000 times. The diameter of the smallest object resolvable by an optical microscope, \( r \), is given by the Abbe equation [Equation 1]:

\[
r = \frac{0.6\lambda}{n \sin \alpha}
\]

where \( \lambda \) is the wavelength of light, \( n \) is the refractive index of the object medium and \( \alpha \) is the half-angle of light collection by the objective lens of the microscope. The quantity \( n \sin \alpha \) is called the numerical aperture (N.A.) and characterizes the ability of objective lenses to resolve small objects. The N.A. of high-power oil immersion objective lenses can be as high as 1.4. As an example, for green light (0.54 µm), the resolution of an N.A. 1.4 objective lens is 0.23 µm.

1.2 Specimen Preparation for Brightfield Microscopy

For useful imaging near the limits of resolution, biological and nonbiological specimens must be prepared as thin films or slices, called sections. Sections of most materials of thickness less than 20 µm are translucent and nearly invisible. Even under the microscope, lack of contrast makes observation of microscopic structure almost impossible unless special optics are used, such as phase contrast microscopy and differential interference contrast (DIC) microscopy. Without such special optics, sections must be heavily stained by addition of strongly absorbing dyes. In medicine and biology, the dyes hematoxylin and eosin (H&E) are most commonly used to stain microscope sections. Hematoxylin is a basic (cationic) dye that binds electrostatically to acidic (anionic) sites of nucleic acids (DNA and RNA). Eosin is an acidic anionic dye that binds to proteins, which become cationic when the staining procedure is performed at pH 4–5. Under the microscope, structures rich in nucleic acids, such as cell nuclei, have the blue color of hematoxylin, whereas protein-rich regions of the cytoplasm display the red staining of eosin.

2 FLUORESCENCE OPTICAL MICROSCOPY

2.1 Fluorescence and Phosphorescence

Staining must be very intense to visualize specimens by brightfield microscopy. This limits sensitivity of brightfield microscopy to observe components of low abundance in a specimen. To improve sensitivity, specimens may be labeled with fluorescent tags. Absorbed light excites these tags to emit photons of longer wavelength. Fluorescence lifetime ranges between tenths of a nanosecond to about 100 ns and reflects the average time between absorbance of the excitation photon and release of the emitted photon. Quenching is any phenomenon that causes decay of the excited state without emission of a photon. Quenching commonly occurs when the energy of the excited state is transferred to solvent molecules and is dissipated as thermal energy. Light absorbance excites some molecules to a triplet state, which persists for hundreds of microseconds or longer before decaying to the ground state. For such molecules, release of a photon upon return to the ground state is called phosphorescence. Specialized fluorescence lifetime microscopes can image fluorescence and phosphorescence based both on lifetime and intensity. Thus, short- and long-lived emitters can be distinguished even if the wavelength of emission is identical.\(^{(1)}\)

2.2 Epi-illumination

In fluorescence (and phosphorescence) microscopy, light of a specific wavelength illuminates the specimen to excite a specific absorbing species. Fluorescence emission is then magnified and imaged by the same basic optics as a conventional brightfield microscope. Special optical filters must be employed both to select the color of the excitation light and to distinguish fluoresced light from the excitation light. In a typical optical arrangement called epi-illumination, a dichroic mirror reflects the excitation light to a bright light source, such as a heated tungsten filament or mercury vapor lamp, into the microscope objective on to the specimen (Figure 1). Excitation light first passes through a barrier filter, which selects the desired wavelength of excitation. For example, a bandpass interference filter transmitting blue light between 470 and 500 nm might be employed to excite the green fluorescence of many fluorophores. Neutral density filters are also often needed to attenuate the excitation light to decrease photodamage and photobleaching. Fluorescence from excited fluorophores in the specimen passes back through the objective lens. Because dichroic mirrors can be constructed to reflect light of shorter wavelengths and transmit longer wavelength light, the dichroic mirror transmits only the fluoresced light, separating it from backscattered excitation light. After passing through another barrier filter, often a long-pass filter that transmits all light longer than a specified wavelength, the fluoresced light is formed into an image to be observed by the eye or recorded by photographic film or video camera. Epi-illumination fluorescence microscopes are very efficient at eliminating stray excitation light. As a result, fluorescence is imaged against a background of almost complete blackness. This accounts for the remarkable sensitivity of fluorescence microscopy to visualize fluorescently tagged specimens.

2.3 Confocal Fluorescence Microscopy

2.3.1 Problem of Imaging Fine Detail in Thick Specimens

Depth of field is the axial distance in the specimen space that is in focus in a single image. For conventional brightfield and fluorescence microscopes, the effective depth of field at high power is 2–3 \(\mu\text{m}\). Since the lateral resolving power of optical microscopy is much greater than this depth of field, superimposition of detail within this field obscures structural detail that might otherwise be resolved. For specimens thicker than a few micrometers, light from out-of-focus planes is also superimposed, further degrading the image. In fluorescence microscopy, this out-of-focus fluorescence creates diffuse halos around in-focus objects under observation. In recent years, the technique of confocal microscopy has evolved to visualize fluorescence arising from only a very thin optical plane through the specimen.\(^{(2)}\) Confocal images achieve submicrometer depths of field with virtually complete
rejection of light from out-of-focus planes. This smaller depth of field and rejection of out-of-focus light together produce images of remarkable detail and quality.

### 2.3.2 Pinhole Principle

The thin optical slices of confocal microscopy are obtained by illuminating one point at a time with a spot of light scanned across the specimen. The microscope objective focuses the illuminating beam, which is typically from a laser, to a tiny spot within the specimen (Figure 2). The diameter of these spots depends upon the wavelength of light and the N.A. of the objective lens (see Equation 1). Fluoresced light returns through the objective lens, and a dichroic mirror again separates the returning light from the illuminating light. After passing through an additional barrier filter, fluorescence is projected by the objective on to a small pinhole. Light originating from the in-focus cross-over point of the illuminating light beam is focused to a small spot precisely at the pinhole. This in-focus fluorescence passes through the pinhole to a light detector beyond, typically a photomultiplier. Fluorescence from above and below the focal plane is projected to spots behind and in front of the pinhole, respectively. As a result, out-of-focus fluorescence is spread out when it reaches the pinhole and does not traverse the pinhole aperture (Figure 2). In this way, the pinhole selectively transmits in-focus light and rejects out-of-focus light.

To create a two-dimensional image, vibrating mirrors in the light path scan the illuminating light beam across the specimen. The mirrors also “descan”, returning fluorescence in order to focus it on the stationary pinhole. Computer memory then stores light detected by the photomultiplier, and a video monitor displays detected fluorescence in register with the movement of the light beam across the specimen.

### 2.3.3 Axial Resolution of Confocal Microscopy

The thickness of a confocal optical section decreases as the pinhole diameter decreases. The limit of resolution occurs when the pinhole becomes smaller than the diffraction limited spot (Airy disk) of in-focus light that is projected on it. Further decreases in pinhole diameter produce no further improvement of axial resolution (section thickness). Axial resolution (Z) at this limit is given by Equation (2):

\[
Z = \frac{2\lambda n}{(N.A.)^2}
\]

Assuming green light (0.54 µm), oil immersion (n = 1.55) and an N.A. of the objective lens of 1.4, the axial resolution is 0.85 µm.

The better axial resolution of confocal microscopy improves the discrimination of individual small objects within a thick specimen, as compared with widefield microscopy. Confocal and nonconfocal images of cultured hepatocytes labeled with Rhodamine 123 illustrate the improvement (Figure 3a and b). Rhodamine 123 is a green-fluorescing cationic fluorophore that accumulates electrophoretically into the negatively charged mitochondria. In hepatocytes, mitochondria are round, oval and sometimes snake-like subcellular organelles of about 1 µm in diameter. When imaged by conventional epifluorescence microscopy, individual mitochondria are easily identified at the cell periphery where the cytoplasm is the thinnest, but in thicker central regions superimposition of detail and out-of-focus fluorescence obscure the definition of the individual organelles (Figure 3a). Rather, an irregular mass of fluorescence occupies the cell center, suggesting falsely that the mitochondria are fused into a larger structure. By contrast, confocal microscopy shows that the mitochondria are well delineated individual structures, and the improvement of useful resolution is immediately obvious (Figure 3b).
ELECTRONIC ABSORPTION AND LUMINESCENCE

2.3.4 Excitation Sources for Confocal Microscopy

In laser scanning confocal microscopy, the type of laser determines the wavelengths available to excite fluorescence: 488 and 514 nm for argon lasers, 543 nm for helium–neon lasers, 488, 568 and 647 nm for argon–krypton lasers and 351–365 nm for ultraviolet (UV)–argon lasers. Some confocal microscope designs employ a white light source. With interference filters, virtually any excitation wavelength can then be selected, but the fluorescence images are generally dimmer than with laser illumination. The wavelength of excitation must be chosen to match the fluorescence excitation spectrum of the fluorophore under study, e.g. 488 nm for fluorescein and 543 or 568 nm for rhodamine. Similarly, dichroic mirrors and barrier filters must be appropriate for the emission spectrum. Sometimes a second dichroic filter is placed in the emission light path so that fluorescence of different wavelengths may be separated and detected. With multiline lasers or a combination of different lasers, specimens tagged with two or more fluorophores may be excited simultaneously. The different colors of fluorescence emission from these fluorophores can then be detected simultaneously using different photomultipliers.

Simultaneous detection of multiple fluorophores is particularly advantageous for comparing dynamic changes of parameters of interest in living specimens.

2.4 Multiphoton Excitation Fluorescence Microscopy

2.4.1 Multiphoton Fluorescence Excitation

If two photons impinge on a fluorophore virtually at the same time, their energy can be absorbed simultaneously to produce fluorescence excitation. The energy yield from absorbance of two photons is equivalent to that of one photon of twice the energy (i.e. half the wavelength). Hence two photons of red light can excite a fluorophore that normally requires UV illumination. Importantly, the rate of two-photon excitation varies with the square of the light intensity, just as the rate of a chemical reaction, \( A + A \rightarrow B \), varies with the square of the concentration of A. Similarly, three-photon and higher order fluorescence excitation can be achieved, which varies with the cube and higher powers of intensity.

2.4.2 Multiphoton Fluorescence Imaging

The nonlinear dependence of multiphoton fluorescence excitation has a very important implication for laser scanning microscopy. As illustrated in Figure 4, the light intensity of a beam of laser light focused by the objective lens is greatest at the cross-over point. As light travels through this cross-over point, the beam spreads out again. Because two-photon excitation is dependent on the square of light intensity, the zone of fluorescence excitation is effectively confined only to the point of highest light flux, namely at the cross-over point. As the beam spreads out, fluorescence excitation drops off rapidly. Thus, as the laser beam is scanned across a specimen, fluorescence arises only from the plane traversed by the cross-over point of the laser beam. The result is a thin optical section, but without the necessity for detection through a pinhole.

A further difference between multiphoton microscopy and pinhole confocal microscopy is that fluorescence need not be imaged through the optics of the microscope.

Simultaneous detection of multiple fluorophores is particularly advantageous for comparing dynamic changes of parameters of interest in living specimens.

(b) Confocal fluorescence micrograph of another rhodamine 123-labeled hepatocyte. Magnification is approximately the same. (Adapted from Lemasters et al.5)

2.4 Multiphoton Excitation Fluorescence Microscopy

2.4.1 Multiphoton Fluorescence Excitation

If two photons impinge on a fluorophore virtually at the same time, their energy can be absorbed simultaneously to produce fluorescence excitation. The energy yield from absorbance of two photons is equivalent to that of one photon of twice the energy (i.e. half the wavelength). Hence two photons of red light can excite a fluorophore that normally requires UV illumination. Importantly, the rate of two-photon excitation varies with the square of the light intensity, just as the rate of a chemical reaction, \( A + A \rightarrow B \), varies with the square of the concentration of A. Similarly, three-photon and higher order fluorescence excitation can be achieved, which varies with the cube and higher powers of intensity.

2.4.2 Multiphoton Fluorescence Imaging

The nonlinear dependence of multiphoton fluorescence excitation has a very important implication for laser scanning microscopy. As illustrated in Figure 4, the light intensity of a beam of laser light focused by the objective lens is greatest at the cross-over point. As light travels through this cross-over point, the beam spreads out again. Because two-photon excitation is dependent on the square of light intensity, the zone of fluorescence excitation is effectively confined only to the point of highest light flux, namely at the cross-over point. As the beam spreads out, fluorescence excitation drops off rapidly. Thus, as the laser beam is scanned across a specimen, fluorescence arises only from the plane traversed by the cross-over point of the laser beam. The result is a thin optical section, but without the necessity for detection through a pinhole.

A further difference between multiphoton microscopy and pinhole confocal microscopy is that fluorescence need not be imaged through the optics of the microscope.

**Figure 4** Scheme illustrating multiphoton excitation at cross-over of the focused laser beam.
Since the region excited by the two-photon phenomenon is intrinsically restricted to the plane of cross-over illumination, light may be collected directly by an external photomultiplier placed near the specimen. This detection configuration avoids light losses that occur when fluorescence is conducted back through the imaging system and scanner.

2.4.3 Laser Sources for Multiphoton Microscopy

To achieve efficient two- and three-photon fluorescence excitation, the instantaneous light intensity must be extremely high. Continuous illumination at such high power would almost instantly destroy specimens. Instead, pulsed lasers are employed to produce brilliant ultrashort 100–300-fs bursts of illumination. The instantaneous light intensity is sufficient to produce multiphoton excitation but the average power is much less because the individual pulses are separated by 10–13-ns intervals (75–100-MHz repetition rate). Currently, the most widely employed laser for multiphoton microscope systems is the pulsed Ti:sapphire laser, which is tunable between 680 and 1000 nm. When tuned to 700 nm, pulsed Ti:sapphire lasers produce two-photon excitation of UV-absorbing fluorophores. Longer wavelengths produce two-photon excitation of fluorescein- and rhodamine-like fluorophores. At 900 nm or greater, the Ti:sapphire laser can also achieve three-photon excitation of UV-absorbing fluorophores with simultaneous two-photon excitation of visible wavelength fluorophores. Modulation of the laser pulse width influences the relative strengths of two- and three-photon excitation. Shorter pulses favor three-photon excitation, whereas longer pulses produce relatively stronger two-photon excitation. 

2.4.4 Advantages of Multiphoton Microscopy Over Confocal Microscopy

Since photons are only absorbed by the target fluorophores at the cross-over point of the laser beam, essentially no photobleaching and photodamage occur above and below the image plane. Moreover, most biological tissue has little intrinsic absorbance of red and infrared (IR) light. Thus, at power levels required for both two- and three-photon excitation, collateral damage is virtually absent even after prolonged exposure. Because light scattering decreases with increasing wavelength and because intrinsic red- and IR-absorbing chromophores are in low abundance, biological tissues transmit red and especially near-IR light very well. Thus, the laser beam for multiphoton excitation penetrates deep into tissues. For both UV and visible wavelength fluorophores, fluorescence imaging deep into tissues by two- and three-photon microscopy becomes possible. This would be simply impossible by conventional one-photon fluorescence microscopy.

Unlike conventional fluorescence microscopy, the wavelength of emitted fluorescence in multiphoton microscopy is shorter than the excitation wavelength. Thus, emitted light scatters more than the excitation light. However, by using a photodetector placed near the specimen outside the microscope optics (nondescanned external detection) or by removing the pinhole from the detection light path, even scattered light can be captured with high efficiency. Such scattered light would not be collected by a conventional confocal microscope.

3 FLUORESCENCE LABELING

3.1 Autofluorescence

The most direct approach in fluorescence microscopy is observation of the intrinsic fluorescence or autofluorescence of specimens. In biology, oxidized flavoproteins, reduced forms of pyridine nucleotides [nicotinamide adenine dinucleotide (reduced form) (NADH) and nicotinamide adenine dinucleotide phosphate (reduced form) (NADPH)] and α-tocopherol (vitamin E) are autofluorescent and can provide useful images. Autofluorescence can also be an undesirable artifact that obscures observation of specific fluorescent tags. Certain preparative techniques produce autofluorescence in biological specimens, particularly chemical cross-linking with glutaraldehyde and other fixatives.

3.2 Immunofluorescence

Much more commonly, specimens are labeled with specific fluorescent tags. In immunocytochemistry, a primary antibody is prepared against a specific cellular constituent, such as a protein or complex carbohydrate. In direct immunocytochemistry, this antibody is reacted with a fluorescent molecule, such as fluorescein or rhodamine isothiocyanate. After treatment of the specimen with the fluorescently labeled antibody, fluorescence microscopy then shows the cellular and subcellular distribution of the constituent of interest (Figure 5a). In indirect immunocytochemistry, the tissue section is first treated with unlabeled primary antibody, such as rabbit immunoglobulin G (IgG). Subsequently, the section is exposed to a fluorescently labeled secondary antibody against the primary antibody, such as goat anti-rabbit antibody (Figure 5b). In general, indirect immunocytochemistry produces brighter fluorescent labeling than direct immunocytochemistry, because several fluorescently tagged secondary antibodies bind to each primary antibody. Other high affinity binding reactions are also
3.3 Parameter-indicating Fluorophores in Living Cells and Tissues

Fluorescence microscopy is becoming an indispensable tool to study cells and tissues in their living state. Although autofluorescence sometimes provides useful signals, in general living specimens must first be labeled with one or more parameter-indicating fluorescent probes. These fluorophores constitute four broad categories: (1) probes of general cell function and integrity, such as cell viability, cell shape and volume, electrical potential, and membrane permeability; (2) markers of specific intracellular structures, such as mitochondria, lysosomes and endoplasmic reticulum; (3) probes of specific chemical species, such as ions, oxygen radicals, and thiols; and (4) fluorescent molecular markers of specific cellular proteins. Table 1 shows a partial list of parameter-indicating fluorophores useful in fluorescence microscopy of living cells.\(^{(9–36)}\) A much more comprehensive listing can be found in Haugland.\(^{(20)}\)

3.3.1 Probes of General Cell Function

3.3.1.1 Cell Viability and Integrity

Cells are normally impermeable to large hydrophilic molecules unless a specific membrane transporter system exists. When cell viability is lost, this permeability barrier breaks down, which allows otherwise impermeant molecules to cross freely into and out of the cell interior.\(^{(9–11)}\) For example, viable cells exclude the cationic fluorophore propidium iodide. When viability is lost, propidium iodide enters cells and binds to nuclear DNA. This binding enhances the red fluorescence of propidium iodide, which is readily visualized by fluorescence microscopy.

Other fluorophores, such as fluorescein and calcein, are retained by viable cells and are released only after loss of cell viability. These fluorophores are loaded into cells as their neutral, membrane-permeant ester derivatives. After the neutral esters have crossed into cells, endogenous esterases release the membrane-impermeant free acid form of the fluorophores, which becomes trapped in the cytoplasm. When cell viability is lost, the trapped dye is released. In theory, cells should retain these fluorophores indefinitely. However, many cells possess transporters that allow these anionic fluorophores to cross the plasma membrane and gradually leak from the cytoplasm. Thus, dye retention may not be as reliable as dye exclusion as an indicator of cell viability.

The fluorophore calcein labels the cytosol when cells are incubated with calcein AM ester at 37 °C. In some cell types, calcein uptake is almost exclusively in the cytosol and the nucleus. Mitochondria exclude calcein and appear by negative contrast as round dark voids in the fluorescence. These voids disappear after mitochondria injury causing increased mitochondrial membrane permeability and uncoupling of oxidative phosphorylation. In this way, redistribution of intracellular calcein can reveal increases of permeability of intracellular membranes.\(^{(12)}\)

3.3.1.2 Cell Volume and Topography

Cell shape, volume and surface topography are essential features

ELECTRONIC ABSORPTION AND LUMINESCENCE

Figure 6 Confocal volume rendering and scanning electron micrograph of cardiac myocytes. (a) Computer-generated volume rendering of a calcein-loaded cardiac myocyte calculated from serial confocal images collected through the entire thickness of the cell. (b) Scanning electron micrograph of another cardiac myocyte at about the same magnification. (Adapted from Chacon et al.\textsuperscript{15})

of cell structure. By labeling the intracellular space of cells with a fluorophore such as calcein, serial confocal images through the entire thickness of individual cells can be used to reconstruct cell volume and shape. Such reconstructions, or volume renderings, employ contour-dependent shading to depict cellular shape and surface detail, as illustrated in Figure 6(a) for a single cardiac myocyte in culture. Such volume renderings rival scanning electron micrographs in the depiction of topographical detail, although electron microscopy achieves superior lateral spatial resolution (Figure 6b). However, confocal fluorescence microscopy permits the repeated imaging of living cells, unlike scanning electron microscopy, which requires that specimens be chemically fixed, dried and coated with metal. Repeated volume renderings also quantify changes of cell volume over time.\textsuperscript{15}

3.3.1.3 Electrical Potential Both the plasma membrane and mitochondria maintain a negative transmembrane electrical potential ($\Delta\Psi$). As a consequence, lipophilic cationic fluorophores such as rhodamine 123 and TMRM accumulate electrophoretically in response to these membrane potentials.\textsuperscript{16,17} Uptake is related to $\Delta\Psi$ by the Nernst equation [Equation 3]:

$$\Delta\Psi = -60 \log \frac{F_{\text{in}}}{F_{\text{out}}}$$

where $F_{\text{in}}$ and $F_{\text{out}}$ represent the concentrations of the monocationic fluorophore inside and outside the membrane, respectively. From Equation (3), uptake ratios of 10, 100 and 1000 : 1 signify $\Delta\Psi$ values of $-60$, $-120$ and $-180$ mV, respectively. $\Delta\Psi$ of the plasma membrane ordinarily ranges between $-30$ and $-90$ mV, depending on cell type, and mitochondrial $\Delta\Psi$ is $-100$ to $-190$ mV. These $\Delta\Psi$ values are additive, such that mitochondria are as much as 240 mV more negative than the extracellular space, corresponding to a fluorophore concentration ratio of 10 000 : 1 inside mitochondria relative to the outside of the cell.

From confocal and multiphoton fluorescence images, average extracellular fluorescence intensity of a potential-indicating fluorophore can be divided into intracellular fluorescence for each picture element or pixel.\textsuperscript{15} By applying the Nernst equation to each pixel, electrical potential of every point inside the cell relative to the extracellular space can be calculated and displayed as a pseudocolor map. Differences in electrical potential across membranes then represent the corresponding transmembrane potentials.

Figure 7 illustrates the intracellular electrical potential measured in a cultured rat hepatocyte. Under the cell surface and in the nucleus, the electrical potential is about $-40$ mV. Since extracellular electrical potential represents the ground (0 mV), $\Delta\Psi$ is $-40$ mV across the plasma membrane. Distributed throughout the cytoplasm are also more electronegative mitochondria with potentials as great as $-160$ mV. Since the electrical potential of the surrounding cytosol is $-40$ mV, the difference, $-120$ mV, represents mitochondrial $\Delta\Psi$. Mitochondria appear to show heterogeneity of electrical potential. This heterogeneity is due, at least in part, to the fact that not
all mitochondria extend completely through the confocal slice, causing electrical potential to be underestimated.

3.3.2 Markers of Specific Intracellular Structures

Many fluorophores tag specific intracellular structures. As discussed above, cationic fluorophores such as rhodamine 123 and TMRM brightly label mitochondria (Figures 3 and 7). Carbocyanine dyes label endoplasmic reticulum and fluorescent ceramide conjugates label the Golgi apparatus. Weak bases, such as LysoTracker Red®, accumulate into acidic lysosomal compartments (Table 1).

3.3.3 Probes of Specific Chemical Species

3.3.3.1 Ion Indicators and Ratio Imaging

Many fluorophores measure ion concentration in individual living cells. Typically, these fluorophores are loaded as their neutral ester derivatives, as described above for calcine. Inside cells, the fluorescence of ion-indicating fluorophores depends on both the ion concentration and the amount of fluorophore present in the light path. When ion binding to a fluorophore causes a red or blue shift of the excitation or emission spectrum, a ratioing procedure may be used to correct for changes in fluorophore concentration (Figure 8). Images are acquired at two different excitation or emission wavelengths: one wavelength that changes with changing ion concentration, and another wavelength that either does not change or changes in the opposite direction. After background subtraction to remove any contribution of nonspecific scattered light and instrumental dark current, the fluorescence image at the first wavelength is divided by the image at the second wavelength on a pixel-by-pixel basis. The result is a ratio image. For example, with 568-nm excitation, the fluorescence of carboxy SNARF-1 emitted at 640 nm increases as the pH increases, but emission at 585 nm does not change. Consequently, the ratio of fluorescence at the two wavelengths is a function of pH but is independent of SNARF-1 concentration. Ratioing eliminates variations in image brightness due to differences of regional fluorophore concentration, dye leakage over time and photobleaching. Using a calibration curve, ratio images are converted to maps of intracellular ion distribution. Not all ion-indicating fluorophores are suitable for this ratioing procedure. Only indicators that have ion-induced spectral shifts, such as Indo-1 and Fura-2 for Ca$^{2+}$, SNARF-1 and BCECF for pH, SBFI for Na$^+$, PBFI for K$^+$ and Mag-Fura for Mg$^{2+}$ (Table 1). Unfortunately, all these dyes except SNARF-1 and BCECF require UV excitation.

3.3.3.2 Ion Indicators and Nonratiometric Indicators

Green-fluorescing Fluo-3 and Fluo-4 and red-fluorescing Rhod-2 are useful visible wavelength indicators of free Ca$^{2+}$ (Table 1). Their binding affinity for Ca$^{2+}$ is in the range 400–500 nM and their fluorescence increases 30–80-fold after Ca$^{2+}$ binding. However, Ca$^{2+}$ binding does not produce a spectral shift. Hence ratio imaging cannot be applied. Nonetheless, Fluo-3, Fluo-4 and Rhod-2 are useful to measure relative changes of free Ca$^{2+}$, especially...
in confocal and multiphoton microscopy which produce uniform optical slices through cells of interest.

**Compartmental Loading of Ion Indicators** Cation-indicating fluorophores are hydrophilic multivalent carboxylic acids that do not cross cellular membranes. To load these indicators, cells are incubated with their uncharged acetate or AM ester. The esters cross the plasma membrane, become de-esterified and are thus trapped in the cytoplasm. Since esterases reside in several different cellular compartments, ion-indicating fluorophores can distribute into several different compartments after ester loading, often in a heterogeneous fashion.

In many cell types, the temperature of ester loading strongly influences the intracellular distribution of various fluorophores. Warm ester loading at 37 °C favors cytosolic uptake, whereas cold ester loading at 4 °C promotes fluorophore entry into both the cytosol and membranous organelles, in particular the mitochondria. Apparently during warm loading, cytosolic esterases hydrolyze the fluorophore esters before they have the chance to diffuse into mitochondria. By contrast, cold temperature slows esterase activity such that esterified probes are able to diffuse across the cytosol and into mitochondria before hydrolysis occurs. The temperature dependence of ester loading varies with cell type and also with the particular fluorophore used. In cardiac myocytes, for example, calcine and Fluo-3, a green-fluorescing Ca^{2+} fluorophore, localize to the cytosol after warm ester loading, whereas Indo-1, a blue-fluorescing Ca^{2+} indicator, and SNARF 1 load into mitochondria even at 37 °C. Anionic fluorophores in the cytosol gradually leak across the plasma membrane through an organic anion carrier, but release of fluorophores localized to mitochondria and other organelles is much slower. Selective release from the cytosol can be used to achieve selective mitochondrial loading of ion-indicating fluorophores. First, cold loading is used to distribute a fluorophore into both the cytosol and the mitochondria. Subsequently, the loaded cells are incubated at 37 °C for several hours. During the warm incubation, fluorophore in the cytosol leaks across the plasma membrane and is lost to the extracellular medium, but fluorophore in the mitochondria and other organelles (chiefly lysosomes) remains. Subsequently, warm ester loading can be used to load a second fluorophore into the cytosol. In this way, one fluorophore enters the cytosol and another fluorophore enters mitochondria and organelles (Figure 9a and b). By using two-color fluorescence microscopy, the fluorescence of the two fluorophores can be independently measured to compare, for example, changes of cytosolic and mitochondrial Ca^{2+} directly.

**Figure 9** Simultaneous loading of fluorophores into different subcellular compartments. The Ca^{2+} indicator Rhod-2 was localized to the mitochondria of a cardiac myocyte by a cold loading–warm incubation protocol. Subsequently, Fluo-2, another Ca^{2+} indicator, was loaded into the cytosol by warm ester loading, then low Na^{+} buffer was added to increase intracellular Ca^{2+} and saturate the Ca^{2+}-dependent fluorescence of both indicators. Rhod 2 fluorescence (a) was present in mitochondria, but not in toxic blebs (double arrows), whereas Fluo 3 fluorescence (b) was diffusely present in both the cytosol and the blebs. 10 ELECTRONIC ABSORPTION AND LUMINESCENCE

**3.3.3.2 Reactive Oxygen Species and Cellular Thiols**

Incomplete reduction of oxygen causes formation of reactive oxygen species (ROS), including superoxide, hydrogen peroxide and hydroxyl radical. ROS are formed during normal metabolism and as a consequence of various pathological processes. Certain nonfluorescent compounds, such as dichlorofluorescin, dihydrorhodamine 123 and hydroethidium, react with ROS to form highly fluorescent derivatives (Table 1). Fluorescence microscopy can then be used to image the rate and subcellular location of ROS formation in single cells. Glutathione and protein thiols are important targets of oxidation by ROS. Monochlorobimane reacts with glutathione and monobromobimane reacts with both glutathione and protein thiols to form fluorescent adducts. These adducts may also be imaged by fluorescence microscopy to quantify the intracellular distribution of protein and nonprotein thiols in single cells.

The oxidation–reduction status of pyridine nucleotides [nicotinamide adenine dinucleotide (oxidized form) \( \text{NAD}^{+} \) and nicotinamide adenine dinucleotide phosphate (oxidized form) \( \text{NADP}^{+} \)] can be conveniently monitored by imaging of autofluorescence. NADH and NADPH, the reduced forms of \( \text{NAD}^{+} \) and \( \text{NADP}^{+} \), are
